The prognosis for diabetic retinopathy used to be dismal. Timely laser photocoagulation as advocated by the Diabetic Retinopathy Study and the ETDRS reduced severe visual loss by 95%. Currently, anti-VEGF therapy can result in even better visual acuity outcomes for eyes with DME. The DRCR has shown that anti-VEGF therapy can also achieve control of PDR without loss of vision or visual field. We are thus on the threshold of a new treatment paradigm for diabetic retinopathy, that of primary pharmacotherapy. However, as in the past, these new treatments can only be offered if the patient presents and keeps follow-up appointments with their ophthalmologist. Even today, many diabetics still become legally blind because they do not present for timely ophthalmological examination and do not achieve excellent control of blood glucose levels and high blood pressure. Control of these systemic factors can significantly delay the onset and progression of retinopathy. Follow-up is even more important when primary pharmacotherapy is used to treat sight-threatening disease in lieu of laser. All of these issues must therefore be considered when planning therapy for diabetic retinopathy.

Although all agree that screening of asymptomatic diabetic patients is critical, the most cost-effective timing remains controversial. It generally is agreed that type 2 diabetics should be examined at the onset of their disease, then yearly thereafter. Type 1 diabetics do not have to be examined until 5 years into their disease course, but no sooner than puberty, then yearly thereafter. If retinopathy is detected, the frequency of examinations should be increased appropriately.

# Ocular Ischemic Syndrome

Jorge A. Fortun

# 6.23

**Definition:** Ocular signs and symptoms secondary to severe, chronic arterial hypoperfusion.

## Key Features

- Visual loss.
- Blot retinal hemorrhages.
- Dilated, beaded retinal veins.
- Decreased ocular perfusion pressure.
- Ocular neovascularization.
- Severe ipsilateral or bilateral carotid artery obstruction.

## Associated Features

- Pain or ocular angina.
- Neovascular glaucoma.
- Mild anterior uveitis.
- Cherry-red spot in macula.
- Cotton-wool spots.
- Spontaneous pulsations of retinal arteries.
- Ischemic optic neuropathy.

## INTRODUCTION

Ocular ischemic syndrome (OIS) encompasses a spectrum of variable signs and symptoms arising from chronic ocular hypoperfusion, usually secondary to severe carotid artery obstruction. Additional names given to this condition include hypoperfusion retinopathy, hypotensive retinopathy, ischemic ocular inflammation,<sup>3</sup> and ischemic oculopathy.<sup>4</sup> In 1963 Kearns and Hollenhorst<sup>1</sup> introduced the term *venous stasis retinopathy* to first describe findings in patients with advanced carotid artery insufficiency. In order to avoid confusion, this term is best avoided, as it has been used by others when referring to nonischemic central retinal vein occlusion (CRVO),<sup>2</sup> an entirely different condition.

## EPIDEMIOLOGY AND PATHOGENESIS

OIS rarely develops before age 50, with a mean age of 65 years at presentation. Men are affected twice as often as women (reflecting the higher incidence of atherosclerotic cardiovascular disease in men) without racial predilection. Bilateral involvement occurs in approximately 20% of cases.<sup>5</sup> The incidence of the syndrome is estimated at 7.5 cases per million population annually, a figure that may be falsely low since the condition can often be clinically mistaken for other vascular diseases.<sup>6</sup>

Approximately 5% of patients who have hemodynamically significant atherosclerotic carotid artery disease develop OIS, with most cases generally showing 90% obstruction of the ipsilateral carotid artery system.<sup>5</sup> Patients with poor collateral circulation between the external and internal carotid systems are susceptible to developing OIS at even lesser degrees of occlusion, whereas those with well-developed collaterals may not develop the syndrome even with total occlusion of the internal carotid artery.<sup>1</sup> Uncommonly, in patients without carotid disease, isolated obstruction of the ipsilateral ophthalmic artery has been reported as a cause for OIS.<sup>12</sup>

The period and extent of the impaired blood flow necessary to develop this syndrome still is not clear. Color Doppler imaging of eyes with OIS has revealed decreased peak systolic flow velocities of the central retinal artery and reversal of flow within the ophthalmic artery. Reversal of the

ophthalmic artery flow represents collateralization to the external carotid artery system as a result of obstructions in the internal carotid artery system. This further contributes to hypoperfusion and subsequent ischemia of the optic nerve, choroid, retinal pigment epithelium, and outer segments of the photoreceptors, likely resulting in the visual loss seen in OIS.<sup>7,8</sup>

## OCULAR MANIFESTATIONS

### Symptoms

A history of transient vision loss is reported by 10%–15% of patients with OIS.<sup>23,25</sup> Decreased visual acuity is present in over 90% of affected patients at initial evaluation.<sup>5</sup> Loss of vision generally occurs gradually, over a period of weeks to months, but can occur abruptly. The severity is variable: 35% of affected eyes at the time of evaluation have a visual acuity of 20/40 (6/12) or better; 30% range from 20/50 (6/15) to 20/400 (6/120); in 35%, acuity is sufficient to count fingers or worse. The absence of light perception is an uncommon finding initially but may develop as a sequela of severe posterior segment ischemia frequently in combination with neovascular glaucoma.<sup>5</sup> Varying patterns of visual field loss, positive visual phenomena, and prolonged recovery of vision after exposure to bright lights are also associated symptoms.<sup>5,23,25</sup> A dull ache over the eye or brow, referred to by some authors as *ocular angina*, is reported in up to 40% of patients with OIS and can result from ischemia of the globe or elevated intraocular pressure (IOP) caused by neovascular glaucoma.<sup>5</sup>

### Anterior Segment

Anterior segment findings in OIS are common and rarely may be the sole ocular manifestation of carotid occlusive disease.<sup>5,24</sup> Anterior segment neovascularization in a nondiabetic patient without evidence of venous occlusive disease or other predisposing cause, is suggestive of OIS. Approximately two-thirds of eyes exhibit neovascularization of the iris at initial examination, with neovascular glaucoma seen in half of these eyes.<sup>5</sup> Despite complete angle closure by fibrovascular proliferation, some patients will demonstrate normal IOP due to decreased aqueous humor production as a result of impaired ciliary body perfusion from carotid occlusion. Anterior uveitis in eyes that have OIS has been well described.<sup>3</sup> Iritis, present in 20% of these eyes, is generally mild. Flare is a more prominent feature than the cellular response, and keratic precipitates are seen infrequently. The possibility of OIS must be considered in patients over 50 years of age who have new-onset iritis. Lens opacification, even formation of a mature cataract, may occur in the end stages of OIS.<sup>5</sup>

### Posterior Segment

Posterior segment signs are more frequent than those in the anterior segment and provide important clinical clues that support the diagnosis of OIS. Numerous changes can be seen in the fundus, including:

- Retinal arterial narrowing.
- Retinal venous dilation without tortuosity.
- Retinal hemorrhages and microaneurysms.
- Neovascularization of the optic disc or retina.
- Cherry-red spot.
- Cotton-wool spots.
- Spontaneous pulsations of the retinal arteries.

Retinal arterial narrowing and straightening, which are associated with areas of focal constriction, are commonly seen in eyes with OIS. Retinal veins may exhibit beading similar to that seen in diabetic retinopathy.

**Fig. 6.23.1 Retinal Vascular Changes in Ocular Ischemic Syndrome.** Narrowed retinal arteries; dilated, minimally tortuous retinal veins; and blot retinal hemorrhages are present in an eye that is affected by ocular ischemic syndrome.

**Fig. 6.23.2 Retinal Hemorrhages in Ocular Ischemic Syndrome.** Dot-and-blot hemorrhages, as well as microaneurysms, are seen commonly in the midperiphery of eyes that are affected by ocular ischemic syndrome.

Retinal veins are often dilated but not characteristically tortuous or only minimally so (Fig. 6.23.1). This latter feature may help to ophthalmoscopically differentiate OIS from CRVO, in which retinal veins are both dilated and often markedly tortuous.

Retinal hemorrhages are seen in 80% of affected eyes. Typically, these are deep retinal hemorrhages of the dot-and-blot variety, though hemorrhages from ruptured microaneurysms and less frequently nerve fiber layer hemorrhages can also be seen. Characteristically, hemorrhages are found in the midperiphery but can extend into the posterior pole (Fig. 6.23.2). Neovascularization, which ranges from mild to severe, may occur on the optic disc in more than one-third of patients who have OIS. Retinal neovascularization has been described in 8% of eyes.<sup>5</sup>

During examination, a cherry-red spot is seen in 12% of eyes with OIS.<sup>5</sup> This finding most commonly occurs as the IOP from neovascular glaucoma exceeds the central retinal artery's perfusion pressure. Cotton-wool spots and spontaneous pulsations of the retinal arteries are each found in 5% of eyes that have the syndrome.<sup>5</sup> They are typically multiple and occur predominantly in the peripapillary region. When not present spontaneously, retinal arterial pulsations can be elicited easily by minimal pressure on the globe, because of the severe diminution in ocular perfusion pressure. In contrast, eyes that have nonischemic CRVO require a normal amount of digital pressure to induce retinal arterial pulsations.<sup>9</sup> Though rarely performed currently, ocular plethysmography can be used to quantitatively assess diminished ocular perfusion pressure in OIS. Ischemic optic neuropathy, which presents with acute, pale swelling of the disc, has been infrequently reported in eyes affected by OIS.<sup>10</sup> Otherwise, the optic disc tends to be normal in appearance, unlike the disc edema seen with central retinal vein occlusion.

## DIAGNOSIS AND ANCILLARY TESTING

In addition to clinical examination, fluorescein angiography can help to establish the diagnosis of OIS. Ideally, a delay in arm-to-choroid and arm-to-retina circulation times is seen, but variation in the location and speed of injection may make these times difficult to assess. However, demonstration of a well-demarcated leading edge of fluorescein dye within a retinal artery is very unusual for a normal eye and suggests ocular hypoperfusion (Fig. 6.23.3). Patchy filling of the choroid that lasts more than 5 seconds is seen in about 60% of eyes with OIS (Fig. 6.23.4).<sup>5</sup>

Other findings on fluorescein angiography include an increased arteriovenous transit time, staining of the retinal vessels, macular edema, retinal capillary nonperfusion, and evidence of microaneurysms (especially in the periphery). The arteriovenous transit time exceeds 11 seconds in approximately 95% of affected eyes.<sup>5</sup> Late staining of retinal vessels, more prominent in arterioles than in venules, is present in about 85% of cases (Fig. 6.23.5).<sup>5</sup>

Electroretinography demonstrates a decrease in both the a-waves and b-waves in eyes that are affected by OIS, in contrast to the sparing of the a-wave found in central retinal artery occlusions.<sup>11</sup> The choroidal and outer retinal ischemia of eyes with global hypoperfusion accounts for this difference.

**Fig. 6.23.3 Fluorescein Angiography, Ocular Ischemic Syndrome.** A distinctly abnormal finding in a fluorescein angiogram of eyes that are affected by ocular ischemic syndrome is a well-demarcated leading edge of dye within the retinal arteries.

**Fig. 6.23.4 Patchy Choroidal Filling, Ocular Ischemic Syndrome.** Patchy choroidal filling that lasts more than 5 seconds occurs in about 60% of eyes affected by ocular ischemic syndrome.

**Fig. 6.23.5 Staining of Retinal Arteries, Ocular Ischemic Syndrome.** Prominent staining of retinal arteries, rather than venules, can help to differentiate an eye that has ocular ischemic syndrome from an eye that is affected by a nonischemic central retinal vein occlusion (which shows more prominent staining of the venules).

**TABLE 6.23.1 Features That Distinguish Ocular Ischemic Syndrome**

Feature	Ocular Ischemic Syndrome	Nonischemic Central Retinal Vein Occlusion	Diabetic Retinopathy
Laterality	80% unilateral	Unilateral	Bilateral
Age (years)	50–80	50–80	Variable
<b>Fundus Signs</b>			
Veins	Dilated, nontortuous	Dilated, tortuous	Dilated, beaded
Optic disc	Normal	Swollen	Normal
Retinal artery perfusion pressure	Decreased	Normal	Normal
Retinal hemorrhages	Mild	Mild to severe	Mild to moderate
Microaneurysms	Midperiphery	Variable	Posterior pole
Hard exudates	Absent unless in association with diabetes	Rare	Common
<b>Fluorescein Angiography</b>			
Choroidal filling	Delayed, patchy	Normal	Normal
Arteriovenous transit time	Prolonged	Prolonged	Normal
Retinal vessel staining	Prominent arterial staining	Prominent venous staining	Absent (usually)
Clinical signs and fluorescein angiography that help differentiate ocular ischemic syndrome from nonischemic central retinal vein occlusions or diabetic retinopathy.			

Color Doppler imaging is an excellent noninvasive means by which to assess the velocity of blood flow in the retrobulbar circulation. Diminution of blood flow velocities in the central retinal artery, choroidal vessels, and ophthalmic artery is typical. Reversal of flow in the ophthalmic artery is common also. Color Doppler imaging may be used to assess the carotid arteries simultaneously.

Carotid arteriography discloses generally a 90% or greater obstruction of the ipsilateral carotid artery in patients who have OIS.<sup>5</sup> Approximately 50% of eyes are associated with a 100% ipsilateral carotid artery stenosis, whereas in 10% there is a bilateral 100% carotid stenosis. If noninvasive carotid artery evaluation is unremarkable in an eye that shows signs suggestive of ocular ischemia, conventional carotid arteriography or digital subtraction angiography may be required to demonstrate possible chronic obstruction of the ophthalmic artery.<sup>11–13</sup> Rarely, cases of ocular ischemia may be induced by a more distal obstruction in the ophthalmic artery or even within the central retinal artery.

## DIFFERENTIAL DIAGNOSIS

Nonischemic CRVO and diabetic retinopathy are the conditions most likely to be confused with OIS. Various ocular signs help to differentiate these conditions (Table 6.23.1). One particularly useful differentiating feature is

a swollen optic disc, which typically is seen in nonischemic vein occlusions but not in OIS. Additionally, in eyes with CRVO the retinal veins will be dilated and tortuous, whereas in eyes with OIS there is venous dilation but only minimal or no tortuosity. Although microaneurysms may occur in both diabetic retinopathy and OIS, in diabetes they tend to involve the posterior pole preferentially. On rare occasions, giant cell arteritis may induce findings similar to those of OIS. In general, however, giant cell arteritis has a much more dramatic clinical picture, with ischemic optic neuropathy or retinal artery occlusion or both.

## SYSTEMIC ASSOCIATIONS

The atherosclerosis that affects the carotid artery sufficiently to cause OIS is generally widespread. Of patients who have OIS, 50% show evidence of ischemic heart disease and 25% have a history of previous cerebrovascular accidents.<sup>14</sup>

Additional risk factors for both atherosclerosis and arteriosclerosis are found in these patients, such as systemic arterial hypertension, which is found in two-thirds of patients who have OIS, and diabetes mellitus, which is observed in more than 50% of these patients.<sup>14</sup> An examination for hyperlipidemia should be undertaken unless the patient is also under therapy for this condition.

A 5-year mortality of 40% in patients who have OIS reflects the severity of their systemic vascular disease.<sup>14</sup> The main cause of death in these patients is ischemic heart disease, with stroke the second most common cause. Thus, referral for a cardiac evaluation should be considered if it has not been performed recently.

## PATHOLOGY

In the early stage of the OIS, the neural retina shows coagulative necrosis of its inner layers, which are supplied by the retinal arterioles. If the area of coagulative necrosis is small and localized, it appears clinically as a cotton-wool spot, a microinfarct of the nerve fiber layer. Histologically, the swollen end-bulbs of the infarcted nerve fiber layer superficially resemble cells, hence the term *cytoid body*. If the area of coagulative necrosis is extensive, it appears clinically as a gray neural retinal area, blotting out the background choroidal pattern. With complete coagulative necrosis of the posterior pole (e.g., after a central retinal artery occlusion), the red choroid shows through the central fovea as a cherry-red spot. The inner half of the neural retina becomes “homogenized” into a diffuse, relatively acellular zone. Generally, thick-walled retinal blood vessels are present.

## TREATMENT, COURSE, AND OUTCOME

Patients with mild OIS may maintain excellent vision, but the natural course of eyes that have more severe disease is quite poor.<sup>15</sup> Assessment of carotid artery function in patients with OIS is of utmost importance. The North American Symptomatic Carotid Endarterectomy Trial demonstrated that carotid endarterectomy was beneficial for patients with carotid stenosis of 70%–99% with a recent history of amaurosis fugax, a hemispheric transient ischemic attack, or a nondisabling stroke. The cumulative risk of ipsilateral stroke was 26% after 2 years for patients receiving antiplatelet treatment, whereas the cumulative risk of stroke was 9% 2 years after endarterectomy.<sup>16</sup> The benefit of endarterectomy was tempered by a 2.1% risk of severe stroke or death during the immediate postoperative period in the patients who underwent surgery versus 0.9% in the antiplatelet group. In symptomatic patients with carotid artery stenosis of 50%–69%, only a moderate reduction in risk of stroke was identified after carotid endarterectomy.<sup>17,18</sup>

Stabilization or improvement in vision has been reported in about 25% of eyes after endarterectomy.<sup>15</sup> Doppler color imaging has shown postoperative normalization of preoperative retrograde ophthalmic artery flow following endarterectomy.<sup>19</sup> Electroretinogram a-waves and b-waves can improve with increased amplitudes following endarterectomy.<sup>20</sup> Occasionally, in eyes that have ciliary body hypoperfusion, complete angle closure, and normal IOP, carotid endarterectomy has resulted in severe glaucoma immediately after surgery. In cases in which 100% obstruction and distal propagation of a thrombus has occurred, bypass procedures, such as superficial temporal artery to middle cerebral artery, have been attempted. Although the vision improves transiently in 20% of such eyes, it usually deteriorates within 1 year of surgery.<sup>15</sup> It is currently uncertain what role carotid artery stenting will play in the management of OIS.<sup>21</sup>

In cases that have iris neovascularization in which the anterior chamber angle is open, panretinal photocoagulation may induce regression of

the rubeosis. Unfortunately, the regression after laser therapy is not as prominent as that seen in patients who have iris neovascularization after CRVO.<sup>22</sup> Intravitreal injection of anti-VEGF agents such as bevacizumab has been shown effective in treating iris neovascularization secondary to OIS and should be considered in the management options.<sup>23,25</sup> Elevated IOP from neovascular glaucoma may require cyclodestructive therapies and/or filtering procedures.

# Hemoglobinopathies

Michael D. Tibbetts, Allen C. Ho

# 6.24

**Definition:** A spectrum of ocular abnormalities, including peripheral “seafan” retinal neovascularization, which results from an inherited defect in the synthesis of the hemoglobin molecule.

## Key Features

- Macular ischemia.
- Retinal vascular peripheral nonperfusion.
- Retinal hemorrhages: “salmon patches,” “iridescent spots,” and “black sunbursts”.
- Peripheral retinal neovascularization: “seafans”.

## Associated Features

- Conjunctival “comma-shaped” capillaries.
- Iris atrophy and posterior synechiae.
- Sickie disc sign.
- Macular depression sign.
- Arteriovenous anastomoses.
- Vitreous hemorrhage.
- Retinal detachment.

## INTRODUCTION

Normal red blood cell hemoglobin comprises four polypeptide globin chains, each associated with a central heme ring (ferroprotoporphyrin).<sup>1</sup> The globin chains consist of two identical pairs of  $\alpha$  and  $\beta$  polypeptide chains. The sickle-cell hemoglobinopathies are characterized by a genetic error in  $\beta$ -chain synthesis, which results in abnormal function of the hemoglobin molecule. In conditions of ischemia and metabolic stress, the imperfect globin chains induce pathological alterations in red blood cell morphology. The altered red blood cells are labeled “sickle cells” because of their crescent shape.

Systemic and ocular sequelae are well described. Interestingly, the severity of systemic symptoms does not typically correlate with the severity of ocular manifestations. The most severe systemic complications are observed in sickle SS disease, whereas severe ocular features are most commonly noted in patients with sickle SC or sickle thalassemia (S-Thal) disease. In general, vision-threatening sequelae of the sickle hemoglobinopathies are secondary to ischemia or peripheral retinal neovascularization.

## EPIDEMIOLOGY AND PATHOGENESIS

Hemoglobinopathies can be characterized by electrophoresis and by the genetic mutations that lead to abnormal amino acid substitutions in the  $\beta$ -globin chain. Normal adult hemoglobin with two normal  $\alpha$  and  $\beta$  chains is termed hemoglobin A. Sickle hemoglobin, known as S, was initially described by Pauling and others in 1949 as a single point mutation that resulted in substitution of the amino acid valine for glutamic acid at the sixth position. The substitution of lysine for glutamic acid at this position results in the manufacture of hemoglobin C. The sickle hemoglobinopathies S and C are only two of many known mutations caused by qualitative errors in globin chain synthesis. Inadequate production of either normal or abnormal globin chains, a quantitative error in globin synthesis, is referred to as thalassemia or Thal.

Since these mutations are inherited, heterozygous or homozygous conditions exist. For example, normal hemoglobin comprises homozygous AA globin chains. Classic sickle cell anemia, or SS disease, usually arises when

parents who have sickle trait (AS) disease each pass on their single abnormal S globin chain mutation. In the United States, African-Americans comprise the majority of patients afflicted by the hemoglobinopathies, with sickle trait (Hb AS) affecting approximately 8% and sickle cell disease (SCD) diagnosed in approximately 0.15%.<sup>2</sup> If hemoglobin S is inherited from one parent and hemoglobin C from another, a double heterozygote form of hemoglobin is created known as sickle SC disease, which is nearly as prevalent as SS disease.<sup>2</sup>

Normal hemoglobin confers pliability to the oval-shaped red blood cells, which allows them to pass easily through the microvasculature where they deliver oxygen. Sickle hemoglobins result in red blood cells with a crescentic, elongated shape, particularly under conditions of hypoxia or acidosis. This causes the blood cells to stack, which further exacerbates local ischemia. A vicious cycle of ischemia, red blood cell sickling, tissue hypoxia, and necrosis is set in motion.

Although sickle SS disease has the most severe systemic manifestations, hemoglobin SC and S-Thal have the most severe ocular manifestations with an earlier age of onset. The reasons for this discrepancy are likely multifactorial. The more severe anemia of SS disease is associated with lower red blood cell counts than those in hemoglobin SC and S-Thal disease. Relative anemia may decrease the viscosity of the remaining red blood cells, thereby causing less sludging in the circulation. Another theory posits that SS disease causes more frequent retinal infarction, whereas the less severe hemoglobinopathies such as SC disease cause more ischemia of the retinal tissues.<sup>3</sup> The retinal ischemia may increase the angiogenic response of vascular endothelial growth factor and stimulate neovascularization as opposed to the retinal necrosis induced by infarction.

Since many of the problems are time dependent, the overall prevalence of ocular complications of sickle disease is unknown. In a large cohort, 6% (49/783) of SS patients had proliferative sickle retinopathy (PSR) on initial examination compared with 32% (172/533) of SC patients.<sup>4</sup> Approximately 40%–43% of hemoglobin SC patients and 14%–20% of hemoglobin SS patients can be expected to develop PSR.<sup>5,6</sup>

## OCULAR MANIFESTATIONS

Nearly all ocular or periocular structures can be affected by the sickle hemoglobinopathies. Classic anterior segment findings include conjunctival “comma-shaped” capillaries, which represent intravascular sludging of sickling red blood cells<sup>7</sup> (Fig. 6.24.1). Sectorial iris atrophy represents

**Fig. 6.24.1** A Classic Anterior Segment Finding in Sickle Eye Disease Are Comma- or “S”-Shaped Conjunctival Capillaries. These vessels represent areas of red blood cell sickling or sludging within the capillary bed. (Courtesy William Tasman, MD.)

**Fig. 6.24.2 Sickle SC Disease.** (A) Macular ischemia with the macular depression sign and perifoveal vascular remodeling. (B) Fluorescein angiogram of the same patient demonstrating an irregular and moth-eaten perifoveal capillary network and vascular telangiectasia. (Courtesy William Tasman, MD.)

**Fig. 6.24.3 Optical Coherence Tomography of Macular Atrophy Secondary to Retinal Arteriolar Occlusion in a Patient With SS Disease.** (A) Macular map (6 mm diameter) digitally created from six standard-resolution optical coherence tomographic images demonstrating marked thinning of the temporal macula including the fovea. (B) Horizontal 6 mm high-resolution optical coherence tomographic macular image. Temporally, the inner retinal layers are atrophic, whereas the outer retinal layers remain normal thickness. (Courtesy Andre Witkin, MD.)

areas of anterior uveal ischemia. A mild anterior chamber cell and flare reaction may be observed secondary to incompetence of the blood–ocular barrier. The anterior segment manifestations generally do not pose significant risks for vision loss.

Posterior segment manifestations of sickle hemoglobinopathies may be observed in the vitreous body, optic disc, retina, and subretinal structures.<sup>8</sup> Vitreous hemorrhage secondary to peripheral retinal neovascularization may develop. The optic disc may demonstrate sludging red blood cells within prepapillary retinal capillaries, which appear as small dark spots or vascular lines on the optic disc head.<sup>9</sup> The “macular depression sign” represents atrophy and thinning of the inner retinal layers, which results in an oval depression of the bright central reflex and may be associated with a decrease in vision<sup>10</sup> (Fig. 6.24.2A). Optical coherence tomography (OCT) has confirmed this finding and demonstrated sparing of the photoreceptors and retinal pigment epithelium<sup>11,12</sup> (Fig. 6.24.3). OCT angiography also showed a correlation between retinal thickness measurements and vascular density of the fovea and parafoveal regions.<sup>13</sup> More debilitating macular ischemia can result in frank macular infarction with an enlarged foveal avascular zone secondary to multiple retinal arteriolar occlusions with an often insidious, progressive course.<sup>14–16</sup> Fluorescein angiography reveals irregularity in or enlargement of the foveal avascular zone, with adjacent areas of retinal capillary nonperfusion and retinal vascular remodeling (see Fig. 6.24.2B). Retinal arterial microaneurysms and cotton-wool spots may also be observed.

Retinal arteriolar sclerosis may be identified in areas in which there is diffuse capillary nonperfusion that reflects prior retinal vascular occlusion. Venous tortuosity is observed in as many as half of all patients who have SS disease and in one-third of patients who have SC disease but is not pathognomonic of sickle retinopathy. Angioid streaks are also described in association with SCD.

Other nonproliferative retinal findings are more characteristic of sickle hemoglobinopathies.<sup>17–19</sup> Salmon-colored retinal hemorrhages are preretinal or superficial intraretinal hemorrhages that occur adjacent to a retinal arteriole and are often found in the equatorial retina (Fig. 6.24.4). Histopathologically, they dissect into the vitreous cavity or into the subretinal space.<sup>20</sup> The salmon hue is attributed to an evolution of color changes—the

**Fig. 6.24.4 An Equatorial “Salmon Patch” Intraretinal Hemorrhage With Periarteriolar Hemorrhage.** These peripheral hemorrhages may lead to retinoschisis cavities lined with iridescent particles that comprise hemoglobin degradation products. The vision is 20/20 (6/6). (Courtesy William Tasman, MD.)

initial presentation is bright red. These hemorrhages result from the rupture of a medium-sized retinal arteriole due to ischemic vasculopathy. They usually resolve with few sequelae, although a retinoschisis cavity lined with iridescent refractile yellow particles may persist.

If the intraretinal hemorrhage dissects into the subneural retinal space and disturbs the retinal pigment epithelium, a black sunburst lesion may result (Fig. 6.24.5). These dark, irregularly shaped, spiculated or stellate lesions are the result of retinal pigment epithelial hyperplasia and intraretinal migration.<sup>20,21</sup> Since they are usually localized to the equatorial retina, the retinal pigment epithelium changes generally do not cause significant visual symptoms.

**Fig. 6.24.5 A Black “Sunburst” Retinal Lesion.** This is caused by a hemorrhage that dissected into the subneural retinal space and disrupted the retinal pigment epithelium, which culminated in pigmentary migration. Note the spiculated borders. (Courtesy William Tasman, MD.)

**Fig. 6.24.6 Peripheral Retina in a Sickle SC Patient.** Partially regressed peripheral retinal neovascularization at the junction of the perfused retina (to the right) and the nonperfused retina (to the far left).

PSR was classified into five stages by Goldberg<sup>18,22</sup>:

- Stage I: Peripheral arteriolar occlusions.
- Stage II: Arteriolar–venular anastomoses.
- Stage III: Neovascular proliferation.
- Stage IV: Vitreous hemorrhage.
- Stage V: Retinal detachment.

This progression of PSR typically occurs in the third or fourth decade of life, but the youngest case of PSR was reported in an 8-year-old patient with SC disease.<sup>23</sup> Peripheral retinal arteriolar occlusion can leave large areas of anterior retinal capillary nonperfusion, which is highlighted well by fluorescein angiography. Curiously, retinal venous occlusion is uncommon in patients who have SCD. Occluded arterioles initially appear dark red but subsequently evolve into “silver wire” vessels. Peripheral arteriolar–venular anastomoses evolve to shunt retinal arterial blood into retinal venules. These anastomoses can be best seen with fluorescein angiography at the junction of perfused and nonperfused retina, typically just peripheral to the equator.

Retinal neovascularization in a seafan configuration is the hallmark of PSR, extending from the border zone of perfused and nonperfused retina (see Fig. 6.24.5, Fig. 6.24.6). Initially, a seafan is supplied by one major feeding retinal arteriole and one major draining retinal venule. Over time,

**Fig. 6.24.7 Fluorescein Angiography.** (A) Wide-field fluorescein angiography of proliferative sickle retinopathy (PSR) demonstrating extensive leakage of dye into the vitreous cavity from the sites of neovascularization. (B) Higher magnification fluorescein angiography of PSR demonstrating peripheral capillary nonperfusion (to the far right), retinal vascular remodeling, arteriovenous communications, and leakage of fluorescein dye into the vitreous cavity from the sites of neovascularization. (Courtesy Alok Bansal, MD.)

an arborization of the neovascular complex occurs. Seafans most commonly are observed in patients who have SC disease or S-Thal disease and are rare in the other hemoglobinopathies.<sup>18,22</sup> Fluorescein angiography demonstrates massive leakage of dye into the vitreous (Fig. 6.24.7). The seafans represent a progressive proliferative retinopathy, which exposes the patient to the risks of vitreous hemorrhage and retinal detachment. Seafans may spontaneously involute, resulting in areas of grayish white fibrovascular tissues that often have residual perfused retinal vessels at their base. About 40%–50% of seafans may undergo some degree of auto-infarction during their course.<sup>5</sup>

Vitreous hemorrhage is a common complication of retinal seafan formation. Patients with limited vitreous hemorrhage experience floaters, whereas those with dense vitreous hemorrhage have sudden severe vision loss. These hemorrhages may clear spontaneously with time or may persist to give ochre-colored vitreous membranes.

Retinal seafans may induce fibrovascular tissue on the surface of the retina that causes traction or rhegmatogenous retinal detachments (Fig. 6.24.8). Circumferential seafan involvement can cause peripheral tractional retinal detachment. In the areas of thin, nonperfused retina, atrophic, stretched retinal holes can develop to create combined traction and rhegmatogenous retinal detachments.

**Fig. 6.24.8 Traction-Rhegmatogenous Retinal Detachment.** A retinal tear has developed at the site of peripheral neovascularization and fibrosis, leading to a combined traction-rhegmatogenous retinal detachment. (Courtesy William Tasman, MD.)

## DIAGNOSIS

Most patients who present with the ophthalmic complications of sickle hemoglobinopathies are aware of their underlying red blood cell abnormality. Patients with SC and S-Thal disease who have minimal systemic manifestations can be completely unaware of their systemic diagnosis when the ocular complications flare. The characteristic history of hemoglobin SS patients—including multiple hospitalizations secondary to painful crises, chronic end-organ damage, multiple infections, and bony abnormalities—may not have been experienced with the other hemoglobinopathies.

Hemoglobin electrophoresis or DNA-based testing is necessary to characterize the abnormal globin chain type. A positive test for sickling, such as the solubility test (e.g., Sickledex), indicates the presence of hemoglobin S but does not distinguish between SS, AS, and double heterozygotes such as S-Thal and SC.<sup>1</sup>

Diagnosis of the ophthalmic manifestations of the sickle hemoglobinopathies is enhanced by careful examination of the conjunctiva, iris, anterior chamber, optic disc, and macula. Indirect ophthalmoscopy and peripheral retinal contact lens biomicroscopy are helpful to delineate retinal hemorrhages and proliferative changes. Fluorescein angiography characterizes macular perfusion and peripheral retinal perfusion. Early seafan formation is highlighted well by fluorescein leakage. Ultra-wide field imaging may be useful to assess peripheral nonperfusion and the stage of retinopathy (see Fig. 6.24.7).<sup>24</sup> Diagnostic ultrasonography can characterize posterior segment anatomy when a media opacity occurs, such as from vitreous hemorrhage or ochre membranes. OCT may demonstrate macular thinning with selective loss of the retinal ganglion cell and nerve fiber layer even in asymptomatic SCD patients.<sup>25</sup> OCT angiography may show abnormalities in the parafoveal vascular system that is more common in patients with SC disease and proliferative retinopathy.<sup>13</sup>

## DIFFERENTIAL DIAGNOSIS

Other causes of macular ischemia and peripheral retinal neovascularization, vitreous hemorrhage, and neural retinal detachment are listed in Box 6.24.1.

## SYSTEMIC ASSOCIATIONS

Patients who have classic sickle SS disease manifest a variety of systemic abnormalities, which include anemia, bone marrow infarcts, bony sclerosis (e.g., vertebral “fishmouthing”), aseptic necrosis of the femoral head, ischemia to visceral organs, shortness of breath caused by pulmonary infarcts, and an increase in susceptibility to bacterial infections, particularly salmonellosis caused by reticuloendothelial cell dysfunction. Other hemoglobinopathies result in less severe systemic disease with a mild anemia as the only manifestation.

### BOX 6.24.1 Differential Diagnosis of Hemoglobinopathies

#### Other Causes of Macular Ischemia

- Diabetic retinopathy
- Retinal vascular obstruction
- Embolic phenomena such as talc retinopathy

#### Other Causes of Peripheral Retinal Neovascularization, Vitreous Hemorrhage, and Retinal Detachment

- Proliferative diabetic retinopathy
- Retinal vein obstruction
- The ocular ischemic syndrome
- Sarcoidosis
- Pars planitis
- Retinopathy of prematurity
- Familial exudative vitreoretinopathy
- Eales' disease

## TREATMENT

Advances in treatment have reduced the morbidity and increased the life expectancy of patients with SCD over the last 40 years.<sup>26</sup> Most notably, hydroxyurea therapy has been shown to reduce morbidity and mortality by boosting levels of fetal hemoglobin (HbF).<sup>27</sup> In addition, stem cell transplantation in both children and adults with severe disease can reverse the sickle cell phenotype, and gene therapy is under active investigation.<sup>28,29</sup>

For the ocular manifestations of SCD, treatment efforts focus on altering the course of PSR to reduce the chance of vitreous hemorrhage and retinal detachment.<sup>17</sup> Cryotherapy, diathermy, xenon arc photocoagulation, and argon laser photocoagulation all have been employed to treat peripheral retinal neovascularization. Cryotherapy has been used to treat peripheral retinal neovascularization in the presence of vitreous hemorrhage when the neovascular proliferation is only partially visualized and when vitreous hemorrhage precludes treatment with laser photocoagulation. In recent years, cryotherapy has largely been abandoned because of the significant complication rate.

Various methods of laser photocoagulation effectively induce regression of peripheral neovascularization.<sup>30–34</sup> Feeder-vessel laser photocoagulation requires intensive treatment with high energy but is more likely to be complicated by chorioretinal or choriovitreal neovascularization, retinal detachment, and vitreous hemorrhage.<sup>35</sup> Scatter laser photocoagulation of areas that surround seafan proliferation and associated areas of ischemic retina can induce lesion regression. The rationale is to ablate areas of ischemic retina that are stimulating neovascular proliferation. This hypothesis is supported by studies demonstrating hypoxia-inducible factor 1 $\alpha$  and vascular endothelial growth factor (VEGF) were strongly expressed in retinal cells within avascular (nonperfused) retina in patients with proliferative sickle cell retinopathy.<sup>36</sup> Scatter laser photocoagulation can be performed as a localized treatment confined to areas anterior to the patent neovascular fronds or in a 360° peripheral, circumferential retinal scatter technique to the anterior retina.<sup>30,33,35</sup> The rationale of the 360° scatter treatment is to induce regression of existing peripheral retinal neovascularization and to prevent the formation of any future neovascularization. These techniques can be performed with light to moderate intensity burns approximately 500  $\mu$ m in diameter placed approximately one burn width apart. Scatter laser photocoagulation, either localized or circumferential, is the treatment of choice to prevent complications secondary to peripheral seafan proliferation.

Vitreous hemorrhage secondary to PSR may be followed for up to 6 months to await spontaneous clearing. If areas of retinal neovascularization can be identified through the vitreous hemorrhage, the associated anterior retina should be treated with scatter laser photocoagulation. When the retina is not well visualized, it is important to follow these eyes with ultrasonography, although a minority of patients progress to retinal detachment.

Anti-vascular endothelial growth factor (VEGF) agents have gained increasing roles in the management of many retinal vascular diseases, but their utility in SCD has not been fully investigated.<sup>2</sup> Case reports have described the regression of retinal neovascularization and resolution of vitreous hemorrhage following intravitreal injection of bevacizumab or ranibizumab.<sup>37,38</sup> However, there are no large-scale studies to assess the long-term effects and incidence of complications.

Surgery on patients who have sickle hemoglobinopathies is fraught with ocular and systemic pitfalls. Systemically, a preoperative workup to assess the severity of anemia, hemoglobin electrophoretic status, and overall systemic condition is critical. Intraoperative and postoperative systemic complications include thromboembolic events such as pulmonary or cerebral embolism. Prophylactic exchange transfusions to increase levels of hemoglobin A may reduce the rate of anterior segment ischemia and optic nerve and macular infarcts. However, studies suggest that exchange transfusions are not needed with modern vitreoretinal surgical techniques.<sup>39</sup>

Adequate hydration and supplemental oxygen often are administered during the perioperative periods. If possible, surgery should be performed under monitored local anesthesia. Vasoconstrictive agents, such as epinephrine in the anesthetic block and pupillary dilating agents, should be avoided. Many advocate lowered intraocular pressure (IOP) to both maximize intraocular perfusion and avoid hemoconcentration. Single doses of carbonic anhydrase inhibitors or intravenous mannitol may be administered to lower IOP but should not be used repetitively.

Anterior segment ischemia does not usually occur if care is taken to avoid elevations of IOP and if the anterior ciliary circulation is not violated.<sup>40</sup> The possibility of anterior segment ischemia is reduced by avoiding treatments in the horizontal meridians, which harbor the long posterior ciliary arteries and avoiding transection of the horizontal and vertical rectus muscles. With current vitrectomy instrumentation, fluctuations in IOP during vitrectomy surgery are less common. An ultrasound to elucidate the intraocular anatomy is important in cases of vitreous hemorrhage. The peripheral vitreous may be firmly attached to shallow areas of traction retinal detachment at the sites of fibrovascular proliferation and may not be well visualized intraoperatively.

In cases of combined traction-rhegmatogenous retinal detachment, the surgical goals include the release of areas of traction that elevate the retina as well as the removal of fibrovascular proliferation. Once the retina is flat, scatter endolaser photocoagulation is performed. Postoperatively, the patient's IOP must be monitored closely, particularly if intraocular gas is used.

Patients with sickle hemoglobinopathies who develop postoperative or posttraumatic hyphema are at risk for posterior segment ischemia or infarction even at mildly elevated IOPs. Low oxygen tension and high ascorbic acid levels in the anterior chamber promote sickling of red blood cells, which then can obstruct the trabecular meshwork and lead to a greater elevation of IOP. Aggressive lowering of IOP to less than 25 mm Hg is indicated, with some authors recommending early paracentesis to reduce the IOP in acute situations.

## COURSE AND OUTCOME

The course for patients who have ocular complications secondary to sickle hemoglobinopathies is variable.<sup>26,41,42</sup> Untreated, the incidence of blindness

from PSR is about 12%.<sup>5</sup> Advancements in systemic therapy as well as modern laser and vitrectomy techniques have reduced the risk of vision loss.<sup>43,44</sup> Patients who require intraocular surgery for vitreous hemorrhage or retinal detachment have a higher risk of systemic and postoperative ocular complications, including anterior segment ischemia and optic disc or macular infarction. Patients whose PSR is rendered quiescent with laser photocoagulation may enjoy excellent vision in the long term. In one study of long-term follow-up following laser photocoagulation, only 4% of treated eyes had a repeat vitreous hemorrhage versus 66% of untreated eyes, and severe visual loss in both groups was rare.<sup>42</sup>

# Coats' Disease and Retinal Telangiectasia

*Ferhina S. Ali, Diana V. Do, Julia A. Haller*

# 6.25

**IN THIS CHAPTER**  
Additional content  
available online at  
[ExpertConsult.com](http://ExpertConsult.com)

**Definition:** A localized, congenital, retinal vascular disorder consisting of abnormal telangiectatic segments of blood vessels that result in leakage.

## Key Features

- Retinal telangiectasia.
- Retinal capillary nonperfusion.
- Dilated intercapillary spaces.
- Lipid exudate.
- Subretinal fluid.

## Associated Features

- Usually unilateral.
- Male predominance.
- Fibrovascular macular scars.
- Leukokoria.
- Rare systemic associations, especially muscular dystrophies.

## INTRODUCTION

Retinal telangiectasia is found in a wide range of ocular disease processes. Most retinal telangiectases are acquired secondary to local or systemic conditions such as branch retinal vein occlusion and diabetic retinopathy. Primary retinal telangiectasia is found in Coats' disease, Leber's miliary aneurysms, idiopathic juxtafoveal telangiectasia, and other angiomatous diseases.

## EPIDEMIOLOGY

Coats' disease, described by Coats<sup>1</sup> in 1908, affects men three times as often as women, has no reported racial or ethnic predilection, and is usually unilateral, although as many as 10% to 15% of cases may be bilateral. The average age at diagnosis is 8–16 years, although the disease has been described in patients as young as 4 months. Approximately two-thirds of juvenile cases present before age 10 years. Coats' disease can also be diagnosed in adulthood.

Although it does not appear to be inherited, recent reports implicate genetic mutations in the development of Coats' disease. Cremers and associates found that 55% of cases with retinitis pigmentosa and Coats'-like exudative vasculopathy contained a mutation in the *CRB1* gene.<sup>2,3</sup> Several reports implicate a deficiency of norrin, a retinal protein, in the pathogenesis of Coats' disease.<sup>4,5</sup> Analysis of archival tissue from nine enucleated eyes from males with unilateral Coats' disease revealed a mutation in the *NDP* gene on chromosome Xp11.2 in one subject. Berger and coworkers<sup>6,7</sup> developed a mutant mouse line with the Norrie's disease model and demonstrated abnormalities of the retinal vessels, including telangiectasia, bulb-like dilatations, and underdevelopment of the capillary bed. He and colleagues reported elevated intraocular levels of vascular endothelial growth factor (VEGF) in four eyes with Coats' disease.<sup>8</sup>

## OCULAR MANIFESTATIONS

Coats' disease is characterized by discrete zones of alteration in the retinal vascular structure with aneurysmal dilatation, capillary dropout, and leakage. Vision may decrease as a result of leakage from the abnormal vascular channels that are formed, with consequent edema, lipid deposition, and exudative retinal detachment. The typical fundus picture of Coats' disease is one of retinal vascular abnormalities associated with localized lipid deposition and varying degrees of subneural retinal exudate (Fig. 6.25.1). Vessels may appear sheathed and telangiectatic, and they may have aneurysms that are grape like, clustered, or lightbulb shaped. Often the vessels are adjacent to areas that lack normal capillaries (Fig. 6.25.2). The severity of vascular malformation parallels the degree of surrounding neural retinal thickening, exudation, hemorrhage, and destruction of small vessels. Aberrant arteriovenous communicating channels are frequently present, and occasionally true retinal neovascularization occurs. Leakage from the abnormal vascular bed produces a cloudy subretinal exudate that gravitates toward the posterior pole. As the serous component of the exudate is resorbed by retinal vessels, the lipid-rich yellowish component is left beneath and within the outer neural retinal layers.<sup>9</sup> Over long periods, this yellow exudate may stimulate the ingrowth of blood vessels and fibrous scar tissue (Fig. 6.25.3). The vascular abnormalities occur more commonly superotemporally; they also are found in the macular and paramacular areas. On average, two quadrants of retina are found to be affected at the initial diagnosis in older patients, but young patients may have more serious disease and more extensive retinal involvement. In more advanced and severe cases of Coats' disease, exudative retinal detachment develops (Fig. 6.25.4).<sup>10</sup>

The clinical course is variable but generally progressive. Acute exacerbations of the disease may be interspersed with more quiescent stages. Spontaneous remissions have been reported, with spontaneous occlusion of the vessels and resorption of the exudate, but these are the exception. Secondary complications include neovascularization, vitreous hemorrhage,

**Fig. 6.25.1 Coats' Disease.** Note the typical vascular abnormalities with aneurysmal dilatation, telangiectasia, exudation, and severe lipid deposition in the macula.

**Fig. 6.25.2 Vessels May Appear Sheathed, Dilated, and Telangiectatic or Feature Grape-Like Bunches of Aneurysms.** Vascular changes that are saccular and lightbulb shaped may be seen as well.

**Fig. 6.25.3 Long-Standing Submacular Exudate.** This may stimulate ingrowth of blood vessels or fibrous tissue, with retinal pigment epithelium migration and hyperplasia and the formation of fibrous scars.

**Fig. 6.25.4 In Children, Coats' Disease May Present as Leukokoria With Advanced Lipid Deposition and Exudative Retinal Detachment.** In this eye, the anterior chamber is shallowed slightly, and the retina is immediately behind the lens.

**Fig. 6.25.5 Fluorescein Angiography of Coats' Disease.** In this eye, extensive vascular changes are seen to extend temporally from the macula, with zones of telangiectasia and aneurysm formation adjacent to a large area of capillary nonperfusion. Beading of the blood vessel walls and anomalous vascular communicating channels are present.

cataract, rubeosis iridis, and neovascular glaucoma, with phthisis bulbi in severe cases.<sup>11,12,13</sup>

## DIAGNOSIS

In children, Coats' disease is typically diagnosed as a result of the recognition of poor vision, strabismus, or leukokoria. In patients with leukokoria, a white pupillary reflex on photographs may be the initially noted abnormality. In these cases, the disease is usually advanced, with extensive lipid deposition and retinal detachment (see Fig. 6.25.4). In adults, the most common presenting complaint with Coats' disease is poor vision.

In advanced cases of Coats' disease, rubeosis iridis, angle-closure glaucoma, and cataract may be present. The diagnosis is confirmed ophthalmoscopically when the typical vascular abnormalities are seen in association with lipid deposition and subretinal exudate. The retinal vascular abnormalities occur in small clusters and include kinked, looped, tortuous, and sheathed vessels of varied and irregular caliber.

## ANCILLARY TESTING

Fluorescein angiography is a useful tool for delineating the nature and extent of the vascular abnormalities present in this disease. Most commonly, numerous areas of telangiectasia and micro- and macroaneurysm formation are seen, with beading of blood vessel walls and anomalous vascular communicating channels (Fig. 6.25.5). Early and persistent dye leakage documents the source of exudation and hemorrhage.<sup>9,14,15</sup> The microvasculature may be diffusely absent, with areas of complete capillary nonperfusion.

Optical coherence tomography (OCT) may also be a useful tool to monitor macular edema associated with Coats' disease. When present, abnormal macular thickness on OCT can be quantitatively determined before and after treatment with laser or pharmacological therapy to gauge the response to a particular therapy. OCT angiography reveals an abnormal foveal avascular zone in the superficial capillary plexus.<sup>16</sup>

## DIFFERENTIAL DIAGNOSIS

The severe juvenile form of Coats' disease, which presents with exudative retinal detachment, must be differentiated from other diseases that cause leukokoria in childhood, including retinoblastoma, retinopathy of prematurity, retinal detachment, persistent hyperplastic primary vitreous, congenital cataract, toxocariasis, incontinentia pigmenti, Norrie's disease, and familial exudative vitreoretinopathy. Gass<sup>9</sup> has pointed out that telangiectatic vessels may appear on the surface of both retinoblastomas and Coats' disease lesions. In retinoblastoma, these dilated vessels are continuous with the large vascular trunks that extend into the tumor; in Coats' disease, the dilated vessels do not extend into the subretinal mass.<sup>9</sup>

Ultrasonography is a convenient, noninvasive test that may distinguish between Coats' disease and retinoblastoma and other entities. The

retinal detachment in Coats' disease typically is exudative, with an absence of the calcifications seen in retinoblastoma. Computed tomography (CT) may help characterize intraocular morphology, quantify subretinal densities, detect calcium, and identify vascularity within the subretinal space through the use of contrast enhancement. Also, CT may help detect other abnormalities within the orbit or intracranial space. Examination of subretinal fluid is used rarely, but it confirms the diagnosis of Coats' disease on the basis of cholesterol crystals and pigment-laden macrophages in the absence of tumor cells.<sup>11</sup>

Less severe stages of Coats' disease, especially in adults, must be differentiated from other disorders that produce vascular changes and exudation. These include inflammatory disorders such as Eales' disease, vasculitis, and collagen vascular disease. Tumors accompanied by exudation may mimic Coats' disease, as may diabetic vasculopathy with lipid deposition, branch retinal vein occlusion with vascular remodeling and edema, rhegmatogenous retinal detachment, radiation retinopathy, idiopathic juxtafoveal telangiectasia, von Hippel disease, angiomas of retina, exophytic capillary hemangioma, and sickle cell retinopathy. In these cases, a thorough review of the systems and medical and family histories usually help differentiate primary from secondary disorders.<sup>11,9,10</sup>

## Idiopathic Juxtafoveal Retinal Telangiectasia

Idiopathic juxtafoveal retinal telangiectasia is a group of disorders initially described by Gass and Oyakawa<sup>17</sup> in 1982. The disease is characterized by onset in adulthood and presentation with mild blurring of central acuity caused by exudate from ectatic retinal capillaries in the juxtafoveal region of one or both eyes. They divided these patients into four categories: groups 1A, 1B, 2, and 3.<sup>17,9</sup>

### Group 1A

Group 1A disease consists of unilateral congenital parafoveal telangiectasia, which typically occurs in men and affects only one eye. Retinal vascular abnormalities are present in a small area, one to two disc areas in diameter, in the temporal half of the macula. Onset of symptoms—with visual loss in the 20/40 (6/12) or better range—typically develops at a mean age of 40 years. Photocoagulation of areas of leakage may help restore acuity.

### Group 1B

Group 1B disease consists of unilateral idiopathic parafoveal telangiectasia, usually found in middle-aged men who have blurring caused by a tiny area of capillary telangiectasia confined to one clock hour at the edge of the foveal avascular zone. Vision is usually 20/25 (6/7) or better. Photocoagulation usually is not considered for these eyes because of the proximity of the leakage to the fovea and the good prognosis without treatment. The lesion may be acquired or may simply be a very small focus of congenital telangiectasia.

### Group 2

Group 2 disease consists of bilateral, acquired, idiopathic parafoveal telangiectasia. This variant affects patients in the fifth and sixth decades; mild blurring of vision occurs in one or both eyes. The patients typically have small, symmetrical areas of capillary dilatation, usually the size of one disc area or less, in both eyes. The vascular changes may be temporal only or may include all or part of the parafoveal nasal retina too. No lipid is deposited, and minimal serous exudation is present. A hallmark is the characteristic gray appearance of the lesions on biomicroscopic examination with occasional glistening white dots in the superficial retina. Red-free photography often highlights these findings best (Figs. 6.25.6 and 6.25.7). These patients also commonly have right-angled retinal venules that drain the capillary abnormalities and are present in the deep or outer retinal layers. Retinal pigment epithelial hyperplasia eventually tends to develop along these venules. In these patients, slow loss of visual acuity over many years is produced by atrophy of the central fovea; patients also may develop subretinal neovascularization, hemorrhagic macular detachment, and retinohoroidal anastomosis.

### Group 3

Bilateral idiopathic perifoveal telangiectasia with capillary occlusion is a rare variant in which adults experience loss of vision because of progressive obliteration of the capillary network, which begins with telangiectasia. The capillaries' aneurysmal malformations are more marked than in the other, milder forms of the disease; no leakage occurs from the capillary bed.

**Fig. 6.25.6 Bilateral Idiopathic Parafoveal Telangiectasia Can Often Best Be Demonstrated With Red-Free Photography.** This eye features capillary abnormalities present for virtually 360° in the parafoveal area. Early transit of the eye demonstrates a plexus of capillary abnormalities ringing the fovea.

**Fig. 6.25.7 Optical Coherence Tomography Findings in Idiopathic Parafoveal Telangiectasia.**

Yannuzzi et al. proposed an updated classification.<sup>18</sup> Broadly classified into Type 1, or unilateral aneurysmal dilation predominantly in men, and Type 2 perifoveal telangiectasia, bilateral telangiectasia limited to the perifoveal area without visible aneurysms but associated with subretinal neovascularization, readily identifiable on OCT angiography.<sup>19</sup>

## The MacTel Project

An international research collaboration comprising more than 30 centers, the MacTel Project, was initiated in 2005 to better understand disease pathogenesis, epidemiology, and potential treatments of idiopathic macular telangiectasia type 2. The MacTel Project found a prevalence of diabetes mellitus of 28% and hypertension of 52% in MacTel type 2, suggesting a vasculopathic etiology of the disease.<sup>20</sup> The project has also identified a genetic susceptibility locus for the disease using gene mapping, but precise genetics of the disease remains unknown.<sup>21</sup> Given the potential for neurodegenerative etiology for type 2 macular telangiectasia, the MacTel Project is investigating the benefits of intraocular delivery of ciliary neurotrophic factor as a treatment for this disease.<sup>22</sup>

## Potential Treatments for Idiopathic Juxtafoveal Retinal Telangiectasia

Several treatment modalities have been explored for group 2 parafoveal telangiectasia. Laser photocoagulation to leaking parafoveal vessels has not been demonstrated to stop the vascular leakage or improve visual acuity.<sup>23</sup> Although intravitreal triamcinolone has been shown to reduce retinal leakage, visual acuity outcomes are variable, and corticosteroid-related adverse events may be limitations with longer follow-up duration.<sup>24</sup> Retrospective and prospective studies of intravitreal injections of anti-VEGF agents such as bevacizumab and ranibizumab have resulted in decreased retinal leakage but not improved vision.<sup>25–30</sup> Therefore VEGF inhibition is not routinely recommended for parafoveal telangiectasia without secondary choroidal neovascularization. If choroidal neovascularization develops, intravitreal anti-VEGF therapy is the most effective therapy available to regress the neovascular tissue.<sup>26</sup>

**Fig. 6.25.8 Initial Photocoagulation of the Eye Shown in Fig. 6.25.5.** Large, medium-intensity spots have been placed on leaking aneurysms, sparing the foveal avascular zone at first. More peripherally, photocoagulation covers temporal aneurysms and is also placed in a scatter pattern in zones of nonperfusion.

**Fig. 6.25.9 Technique Used for Drainage of Subretinal Fluid in Eyes With Extensive Exudative Detachment.** The pediatric infusion cannula is sutured into the anterior chamber through a limbal stab incision with a single Vicryl suture. This is placed in a convenient quadrant so that the eye can be rotated and a posterior draining sclerotomy fashioned. The infusion runs into the anterior chamber and around intact lens zonules, keeping the eye formed as voluminous quantities of thick, yellow subretinal fluid are drained; this subretinal fluid is speckled with cholesterol and lipid deposits.

## SYSTEMIC ASSOCIATIONS

Isolated case reports have described a number of other diseases that occurred simultaneously in patients with Coats' disease. In many cases, it is doubtful that an actual causal association exists. Gass<sup>9</sup> described a patient who had a facial angioma and typical retinal telangiectasia and another who had bilateral retinal disease and progressive facial hemiatrophy. Bilateral telangiectasia and Coats' syndrome have been reported in multiple family members who have facioscapulohumeral muscular dystrophy and deafness. No definite connection has been made between other systemic or ocular conditions and Coats' disease. The adult form of the disease has been described as frequently associated with hypercholesterolemia, although such an association does not occur in the juvenile form.<sup>31,32</sup>

## TREATMENT

The major goal of treatment in Coats' disease is to preserve or improve visual acuity or, when this is impossible, to preserve the anatomical integrity of the eye. Intervention is contemplated when exudation is central and/or extensive and progressive. In severe, untreated cases, total retinal detachment, iris neovascularization with glaucoma, and phthisis bulbi can result. Treatment of Coats' disease is directed toward closure of the abnormal, leaking retinal vessels to allow resorption of exudate. In many cases, the visual results are poor even with successful treatment, especially when the macula is involved initially in the exudative process.<sup>12,31,33–35</sup>

Laser photocoagulation is the treatment of choice in mild to moderate cases of exudation from Coats' disease. Fluorescein angiographic guidance allows precise, localized treatment of the leaking aneurysms and vessels. Lesions that leak are treated directly with relatively large (200–500  $\mu$ m) applications of moderate-intensity light (Fig. 6.25.8).<sup>11</sup> Scatter photocoagulation to areas of extensive nonperfusion are of unproven value but may lessen the chance of secondary neovascularization. Peripheral lesions may be treated with the indirect laser, which may need to be done under general anesthesia in children.

Where subretinal fluid is present, cryotherapy, as opposed to laser, to the anomalous vessels is recommended using a single freeze or freeze-refreeze technique. If the retina is highly elevated, it may be necessary to drain subretinal fluid to flatten the retina and allow sufficient freeze to reach the retinal vessels. In these cases, the retina is flattened, the eye reformed, and cryotherapy or laser applied (Fig. 6.25.9) (Video 6.25.1). Subretinal pigmentation and fibrosis usually ensue and follow the lipid resolution. If this involves the macula, visual return is commensurately poor.<sup>11</sup>

Another approach to eyes with significant retinal detachment is to perform a scleral buckling procedure.<sup>31</sup> Harris<sup>34</sup> reported that a scleral buckle sometimes aids the application of postoperative photocoagulation, because it can be oriented beneath the abnormal vessels, and anomalies at the apex of the buckle can be treated effectively. Siliodor et al.<sup>33</sup> reported

a series of 13 children who had blind eyes and bullous exudative detachments followed either after no treatment or after surgery that involved intraocular infusion, drainage of subretinal fluid, and cryotherapy on one or more occasions. Of the six untreated eyes, four developed painful neovascular glaucoma and underwent enucleation. The seven treated with surgery all remained cosmetically acceptable and comfortable; none developed neovascular glaucoma.

In selected cases of Coats' disease with intravitreal proliferation and traction detachment, vitreous surgery may improve the clinical course. Machemer and Williams<sup>36</sup> reported successful results with surgical removal of vitreal and preretinal membranes and destruction of leaking vessels in a small series of patients.

Repeated therapeutic laser or cryotherapy treatments are typically required in eyes that have Coats' disease. Exudate typically begins to resorb within six weeks of treatment if the abnormal vasculature has been eliminated. Depending on the amount of lipid accumulation, in many cases, it takes months to more than a year for complete resolution. Recurrence of exudate after initially successful treatment signals the development of new abnormal leaking vessels; these must be searched out meticulously. Contact lens biomicroscopy with a three-mirror lens sometimes is a useful adjunct to indirect ophthalmoscopy in these cases, as is wide field fluorescein angiography. Recurrences may occur years after initially successful treatment, so it is particularly important to follow juvenile patients who may develop significant problems if not followed carefully. Egerer et al.<sup>31</sup> recommended that all patients who have Coats' disease should be examined at least twice a year to catch any early recurrent problems that may develop in a small percentage of these patients.

Intravitreal triamcinolone has been reported to give short-term benefit in select cases of Coats' disease. Othman and colleagues combined intravitreal triamcinolone with either laser photocoagulation or cryotherapy in 15 eyes and found that treatment resulted in reabsorption of subretinal fluid and macular exudates.<sup>37</sup> Other published reports demonstrate improvement in visual acuity and decrease in retinal thickness after intravitreal triamcinolone.<sup>38</sup> More recently, pharmacological therapy with intravitreal inhibitors of VEGF have been reported to have biological activity in Coats' disease.<sup>39–43</sup> Ramasubramanian and Shields reported a retrospective analysis of eight patients with Coats' disease with partial or near total exudative retinal detachment.<sup>40</sup> Treatment with laser photocoagulation and/or cryotherapy plus additional intravitreal bevacizumab (1.25 mg/0.05 ml) with a mean follow-up period of 8.5 months resulted in resolution of retinopathy and subretinal fluid. Vitreous fibrosis in four patients at month five with a traction retinal detachment in three patients was possibly related to the use of intravitreal bevacizumab. Caution is advised when using anti-VEGF therapy for patients with Coats' disease.

## COMPLICATIONS OF TREATMENT

Complications of photocoagulation and cryotherapy for Coats' disease include inflammation, hemorrhage, chorioretinal anastomosis formation, and retinal, chorioretinal, and subretinal fibrosis. Macular distortion secondary to epiretinal membrane formation and contraction has been reported following photocoagulation for Coats' disease and may occur even if the disease is untreated. Gass<sup>9</sup> reported one adult patient who developed total retinal detachment and proliferative vitreoretinopathy after cryotherapy for peripheral retinal telangiectasia that was discovered late in life; the eye initially had 20/20 (6/6) acuity.

With intraocular surgical intervention, additional risks include cataract formation, choroidal hemorrhage, retinal detachment, endophthalmitis, glaucoma, and phthisis.

Intravitreal triamcinolone has been associated with elevated intraocular pressure and cataract progression. Anti-VEGF agents have been associated with retinal fibrosis evolving into traction retinal detachment in case reports.<sup>40</sup> Careful monitoring of patients after administration of pharmacological therapies is advised.

## COURSE AND OUTCOME

The clinical course in Coats' disease is variable, but it is usually progressive. Continued exudation from abnormal vascular channels produces a gradual accumulation of lipid and serous retinal detachment. The downhill course is more rapid in eyes with more extensive vascular abnormalities. Acute exacerbations of the disease may occur with intervening periods of relative stability. The end stage of the exudative process, seen in eyes with severe Coats' disease and particularly in young patients who have an early onset of symptoms, is total retinal detachment, which may be followed by rubeosis iridis, neovascular glaucoma, and eventually phthisis bulbi.

Shields and colleagues conducted a large retrospective review of 150 patients with Coats' disease to determine risk factors for poor visual outcome and enucleation.<sup>44</sup> Risk factors predictive of poor visual outcome (20/200 or worse) were postequatorial, diffuse, or superior location of the telangiectasis and exudation, failed resolution of subretinal fluid after treatment, and presence of retinal macrocysts. Significant risk factors for enucleation included elevated intraocular pressure and iris neovascularization.

The ultimate prognosis for eyes with Coats' disease can be measured in terms of two endpoints: visual acuity and anatomical stability. Unfortunately, central visual acuity is frequently poor in eyes with Coats' disease, because the disease is not diagnosed and treated until after significant macular lipid deposition is present. Even with good treatment and resolution of the macular deposits, significant subretinal fibrosis and macular impairment are present.

Visual acuity results may be quite good in patients who have very mild vascular anomalies that do not require treatment or are discovered and treated before the macula is involved by the exudative process. It is difficult to estimate the frequency with which this situation develops in the general population, because reported series discuss only more severe cases referred to tertiary treatment centers, and the disease is rare enough to have avoided scrutiny in population-based studies.

Eyes with severe exudation and retinal detachment rarely retain vision better than 20/400 (6/120), and many see much worse than this. Nevertheless, successful treatment of leaking vascular channels may salvage some vision, and this has the advantage of stabilizing the eye anatomically. Occasionally an eye may be saved structurally without light perception.

The prognosis for retaining anatomical integrity of the globe is much better. Most eyes with Coats' disease, however, can be saved, be cosmetically acceptable, grow and develop otherwise normally, and in many cases have useful vision. Amblyopia therapy, strabismus surgery, and other types of ancillary rehabilitation may be useful and should not be neglected as part of the total treatment of these patients.

## Radiation Retinopathy and Papillopathy

## 6.26

Ahmet Kaan Gündüz, Carol L. Shields

**Definition:** A slowly progressive occlusive vasculopathy affecting the retina, choroid, and optic nerve, with a delayed onset after irradiation.

**Key Features**

- Retinal microaneurysms.
- Retinal hemorrhages.
- Retinal telangiectatic vessels.
- Retinal hard exudates.
- Macular edema.
- Cotton-wool spots.
- Optic disc swelling.

**Associated Features**

- Retinal neovascularization.
- Disc neovascularization.
- Vitreous hemorrhage.
- Iris neovascularization.
- Optic atrophy.
- Occlusive choroidal vasculopathy.
- Polypoidal choroidal vasculopathy.

**RADIATION RETINOPATHY**

Radiation retinopathy (RR) is characterized by a slowly progressive occlusive vasculopathy with a delayed onset after irradiation.<sup>1</sup> Radiation retinopathy was first described in 1933 by Stallard, who noted retinal exudation, retinal hemorrhage, retinal pigment epithelial changes, and optic disc edema in patients treated with radon seeds for retinal tumors.<sup>2</sup> In 1935, Moore expanded on the initial observations made by Stallard.<sup>3</sup>

RR has been documented after both plaque radiotherapy (also termed *brachytherapy*) and external beam radiotherapy (EBRT) (also termed *teletherapy*) following treatment of intraocular tumors. RR can also develop after EBRT of orbital, paranasal sinus, and intracranial tumors, as well as thyroid ophthalmopathy and orbital inflammation.<sup>1,4</sup> In recent years, a better understanding of the biological effects of ionizing radiation, development of techniques enabling more accurate focusing of radiation to target tissues, and earlier diagnosis and treatment have helped decrease the risk of vision loss resulting from RR.

**Pathology and Pathogenesis**

Histopathological studies of the eyes with RR confirm the predominantly vascular nature of damage produced by radiation therapy. There is an unequivocal loss of endothelial cells with relative sparing of the pericytes.<sup>1,4,5</sup> This is in contrast to diabetic retinopathy, where the target cell is the pericyte instead of endothelial cells.<sup>5</sup>

Radiation basically has two side effects on tissues.<sup>5,6</sup> First, radiation directly damages the endothelial cell DNA. The endothelial cells undergoing mitosis and proliferating at the time of radiation are most vulnerable and eventually succumb to death. As a result of this insult, the remaining endothelial cells migrate and divide in an effort to compensate for the damaged segments. However, if the damage is extensive, there is a relative endothelial cell deficiency, leading to a vasculopathy characterized by vascular leakage, platelet aggregation, and activation of the clotting cascade. Second, the indirect effect of radiation involves creation of free radicals (OH) from water contained within the cell cytoplasm. Free radicals are

highly reactive and induce further DNA damage.<sup>6</sup> The differential sensitivity between endothelial cells and pericytes is the result of direct exposure of endothelial cells to high oxygen and iron found in blood, which generates some of the free radicals.<sup>1,6</sup> Cell damage usually starts on the arterial side of the circulation, where free radical generation is greater because of higher oxygen tension.<sup>1,6</sup> Small retinal vessels are involved first, leading to capillary closure. Larger retinal vessels and choroidal vessels can also be affected later in the course of the disease.

**Clinical Features**

RR is suspected when there is a history of radiation exposure and ocular examination reveals the characteristic fundus findings. RR has a clinical course similar to diabetic retinopathy.<sup>1,7-9</sup> Therefore, it is prudent to classify RR as nonproliferative radiation retinopathy (NPRR), proliferative radiation retinopathy (PRR), and radiation maculopathy (RM) similar to the classification in diabetic retinopathy.<sup>7</sup> In NPRR, retinal capillary changes, retinal edema, retinal hemorrhages, microaneurysms, telangiectatic vessels, hard exudates, vascular sheathing, and cotton-wool spots are evident. When these nonproliferative changes are present within 3 mm of the foveola, the condition is referred to as RM (Fig. 6.26.1). With the development of widespread areas of capillary nonperfusion, retinal and disc neovascularization develop, leading to PRR. If untreated, PRR can result in vitreous hemorrhage, iris neovascularization, and neovascular glaucoma.

Other manifestations of radiation effects on the posterior globe include radiation choroidopathy, including closure of choroidal vessels, leading to choroidal atrophy, polypoidal choroidal vasculopathy, and choroidal infarction.<sup>7</sup> Radiation-related retinal pigment epitheliopathy is another effect that manifests with mottling of the retinal pigment epithelium (RPE), hyperplasia, and eventual atrophy. The term RR is most often used in the literature to broadly encompass all fundus changes, including NPRR, PRR, and RM, as well as radiation choroidopathy and RPE changes.

RR can develop as early as one month to over 15 years after radiation exposure. However, it most commonly occurs between six months and three years.<sup>4</sup> Gündüz et al. reported that 5% of the 1300 patients treated with plaque radiotherapy had NPRR at 1 year and 42% at 5 years.<sup>7</sup> More serious PRR developed in 1% at 1 year and 8% at 5 years.<sup>7</sup> The Collaborative Ocular Melanoma Study (COMS) confirmed these clinical observations and assessed histopathological evidence of RR in enucleated eyes following plaque radiotherapy for melanoma. The authors of that study found that 55% of eyes had evidence of microvascular abnormalities related to RR.<sup>10</sup> Sagoo et al. found that for juxtapapillary melanoma (posterior margin within 1 mm of the optic disc), the risks of RR and RM were higher at 75% and 65%, respectively, after plaque radiotherapy.<sup>11</sup> These studies were based on ophthalmoscopic observations and done mostly before the availability of optical coherence tomography (OCT). Using OCT, Horgan et al. found an increased incidence of macular edema in 40% of eyes by 1 year and in 61% by 2 years after plaque radiotherapy for choroidal melanoma.<sup>12</sup> For proton beam radiation treatment of juxtapapillary and parapapillary melanomas, those located <1 disc diameter from the optic disc, the 5-year rate of RM was 60%.<sup>13</sup> A more recent study evaluating ciliary body as well as choroidal melanomas treated with proton beam irradiation found a 5-year RR rate of 85%.<sup>14</sup>

**Diagnostic Studies**

Fluorescein angiography (FA), OCT, and OCT angiography (OCTA) are diagnostic studies that are most helpful in the evaluation of eyes with RR. FA can demonstrate microvascular changes, capillary dropout, retinal nonperfusion, retinal and disc neovascularization, and macular edema<sup>7-9</sup> (see Fig. 6.26.1; Fig. 6.26.2). It is especially useful in classifying RM as

**Fig. 6.26.1** Radiation maculopathy following plaque radiotherapy for choroidal melanoma (A) showing regressed melanoma inferiorly and retinal telangiectasia, microaneurysms, and exudation in the inferior macula. On fluorescein angiography (B), macular telangiectasia, microaneurysms, and nonperfusion are found. Staining of the optic disc implies radiation-related damage.

**Fig. 6.26.2** Radiation maculopathy with retinal telangiectasia and hemorrhage (A), fluorescein angiographic petaloid staining (B), and optical coherence tomographic outer plexiform cystoid edema (C).

ischemic versus nonischemic. In eyes with ischemic maculopathy, there is little chance for visual improvement with currently available treatment methods. Eyes with nonischemic maculopathy are amenable to treatment, as discussed below.

Using FA, radiation-related macular edema is classified into diffuse, focal, and mixed types based on the pattern of dye leakage. This classification is useful if grid or focal laser treatments are to be applied. Indocyanine green angiography (ICGA) can demonstrate areas of choroidal hypoperfusion; however, this method of angiography is not routinely used in the evaluation of RR.

OCT is a noninvasive procedure that has the advantages of providing quantitative measurement of macular edema. OCT is an important modality in evaluating presymptomatic radiation-induced macular edema (see Fig. 6.26.2). A study by Horgan et al. found that OCT detected evidence of macular edema approximately 5 months earlier than in the case of clinically detected RM.<sup>12</sup> The median visual acuity at the time of OCT-evident macular edema was 20/40. Horgan et al. proposed a five-grade scale for radiation macular edema based on OCT findings:

Grade 1 – noncystoid edema extrafoveal.

Grade 2 – cystoid edema extrafoveal.

Grade 3 – noncystoid edema foveolar.

Grade 4 – cystoid edema foveolar.

Grade 5 – cystoid edema foveolar severe, simulating serous retinal detachment.

Increasing grade of macular edema was found to be associated with worse visual acuity. With the introduction of spectral domain OCT (SD-OCT) technology, better central foveal thickness measurements and superior visualization of the retinal layers became possible.

As a further step in diagnosis of RM, OCTA has come into use. OCTA is a noninvasive technology that can visualize both the superficial and deep capillary plexuses of the retina as well as choroidal vasculature in a noninvasive manner without injection of dye. In contrast, FA can visualize only the superficial retinal plexus and requires dye injection.<sup>15,16</sup> OCTA can demonstrate enlargement of the foveal avascular zone and reduction in parafoveal capillary density of both superficial and deep capillary plexuses as well as parafoveal nonperfusion, capillary dropout, microaneurysms and telangiectasia in eyes with choroidal melanoma after plaque radiotherapy, even in the absence of clinical and SD-OCT evidence of radiation maculopathy.<sup>15,16</sup> The deeper capillary plexus and choroidal vasculature may be affected more because radiation is delivered from the scleral side in plaque radiotherapy (Figs. 6.26.3 and 6.26.4). Therefore OCTA is currently the most sensitive method for detection of early RM and probably for assessment of its severity as well.

Electroretinography (ERG) studies are rarely used in the evaluation of RR and RM. ERG reflects the mass response of retina and may demonstrate decreased amplitudes in widespread RR.

## Risk Factors

### Brachytherapy

Tumor type, thickness, location, radioisotope type, and radiation parameters are important factors to consider in the development of RR following brachytherapy. With plaque radiotherapy, the risk of RR is related to total radiation dose. Total radiation dose is, in turn, related to tumor type. In the treatment of posterior uveal (ciliary body and choroidal) melanoma, therapeutic apical tumor doses range from 80 to 100 Gy, whereas in circumscribed choroidal hemangioma the apical dose is only approximately 20–25 Gy.

Total radiation doses that result in 5% and 50% complication rates at 5 years are defined as tissue tolerance doses—TD<sub>5</sub> and TD<sub>50</sub>. The retina has a TD<sub>5</sub> value of 45 Gy and a TD<sub>50</sub> value of 60 Gy.<sup>17</sup> First, with the therapeutic apical doses used for uveal melanoma, the retina and the macula are inevitably exposed to radiation doses in excess of the normal tissue tolerance doses discussed above. Therefore, RR is seen more often after brachytherapy for choroidal melanoma than that for similar-sized choroidal hemangioma because of the higher radiation dose used in the treatment for melanoma. Second, tumor thickness >4 mm has also been associated with a greater risk of RM.<sup>18</sup> The spillover radiation dose delivered to the surrounding retina is greater with increasing tumor thickness. Third, tumor location is a factor in the development of visually significant RM. Brown et al. found that RM did not develop if the fovea received a dose of ≤50 Gy in brachytherapy.<sup>8</sup> A subsequent study by Gündüz et al. validated this finding.<sup>7</sup> With brachytherapy for peripheral tumors, the fovea receives a smaller radiation dose, and the risk for RM is less. A number of radioactive isotopes, including cobalt-60, iridium-192, ruthenium-106, iodine-125, and palladium-103, have been used in ocular brachytherapy. Of these, the use of cobalt-60 and iridium-192 has been almost totally abandoned because of the higher energy and marked radiation side effects of these radioisotopes. Radiation parameters including tumor apex dose >90 Gy, apex dose rate >75 cGy/hr, and base dose rate >260 cGy/hr were found to lead to RR on a univariate model in one study.<sup>7</sup> Coexisting morbidities, including diabetes mellitus, and concurrent chemotherapy increase the risk of RR in both teletherapy and brachytherapy.<sup>4</sup>

### Teletherapy

Total radiation dose, fractionation, field design, and type and rate of administration are factors that affect the development of RR after EBRT. RR has

**Fig. 6.26.3** Mild radiation maculopathy after plaque radiotherapy. Color fundus photographs show temporally located small, biopsy-proven irradiated juxtapapillary choroidal melanoma in the right eye (A) and normal fellow eye (B). Note the nerve fiber layer infarctions in the papillomacular region and superior macular region of the right eye (A). Spectral-domain optical coherence tomography (SD-OCT) of the right eye after irradiation shows regular foveal contour and normal central macular thickness with no evidence of intraretinal edema or subretinal fluid (C). There is retinal thinning in the papillomacular region from previous subretinal fluid and the vertical bright line through the retina marks the site of needle biopsy (C). Normal SD-OCT findings in the left eye (D).

**Fig. 6.26.3, cont'd** Optical coherence tomography angiography (OCTA; 3-mm scan) of the superficial capillary plexus shows decreased capillary density and widening of the foveal avascular zone (FAZ) in the irradiated right eye (E) compared with the normal fellow eye (F). OCTA (3-mm scan) of deep capillary plexus shows similar findings, including decreased capillary density and widening of the FAZ in the irradiated right eye (G) compared with the normal fellow eye (H).

been seen following EBRT doses ranging from 15 to 60 Gy. However, RR usually occurs with doses  $>45$  Gy. Hyperfractionation is associated with a decreased incidence of RR,<sup>19</sup> and patients who received fractions of  $<1.9$  Gy are unlikely to develop RR, as found in one study.<sup>19</sup> When the treatment site is closer to the eye, the incidence of RR is higher. With respect to proton beam radiotherapy of posterior uveal melanoma, the risk factors for development of RR include posterior tumor margin  $<3$  mm to fovea and optic nerve, larger tumor base diameter, and increased tumor thickness, as reported in one study.<sup>14</sup>

## Differential Diagnosis

RR can be clinically indistinguishable from changes seen in patients with diabetic retinopathy. Other conditions that need to be considered in the top differential diagnosis include branch retinal vein occlusion, central retinal vein occlusion, hypertensive retinopathy, Coats' disease, and perifoveal telangiectasia.

## Treatment

Prevention, if possible, is better than treatment. Unfortunately, RR is an inevitable side effect of radiotherapy, and complete prevention is not possible. However, a number of strategies have been developed to decrease the dose of radiation and hence the risk of development of RR because once macular ischemia develops, vision loss is irreversible.

## Reducing the Dose of Radiation

For brachytherapy, the use of collimating plaques as well as eccentric positioning of the plaques so that the posterior plaque edge is aligned with the posterior tumor margin may help decrease the radiation dose to the macula. Further measures include de-escalating (lowering) the apex tumor dose (to 63 Gy) in an effort to reduce the total radiation dose to macula<sup>20</sup> and filling the vitreous cavity with silicone oil to attenuate intraocular radiation.<sup>21</sup> For teletherapy, appropriate shielding of the ocular structures during EBRT can minimize radiation exposure. As previously mentioned, hyperfractionation of EBRT has been associated with decreased incidence of RR.

## Laser Photocoagulation

Focal/grid macular laser photocoagulation has been used to treat RM, sector scatter and panretinal laser for severe NPRR and PRR, and circumferential laser around the tumor to prevent or delay RM and RR. Focal/grid macular laser photocoagulation has been used to treat RM with variable success. Studies by Kinyoun et al. and Hykin et al. demonstrated a benefit in visual acuity following treatment.<sup>9,22</sup> However, the effect was not sustained with longer follow-up in the study by Hykin et al.<sup>22</sup>

Sector scatter and panretinal laser photocoagulation has been widely used to treat NPRR and PRR after plaque radiotherapy (Fig. 6.26.5). Bianciotto et al. reported that 66% of eyes that underwent panretinal photocoagulation had complete resolution of PRR.<sup>23</sup> In a study by Finger et al., eyes with choroidal melanoma treated by plaque radiotherapy received

**Fig 6.26.4** Severe radiation maculopathy after plaque radiotherapy for biopsy-proven choroidal melanoma. Composite color fundus photograph shows juxtapapillary melanoma located superotemporal to the optic disc, sector laser photocoagulation scars, choroidal atrophy from plaque irradiation, and radiation maculopathy and retinopathy (A). Optical coherence tomography angiography (OCTA; 6-mm scan) of the superficial capillary plexus shows widening of the foveal avascular zone (FAZ), reduced capillary density, microaneurysms, and nonperfusion superiorly (B). OCTA (6-mm scan) of deep capillary plexus shows similar findings, including widening of the FAZ, reduced capillary density, and microaneurysms, but more pronounced macular nonperfusion superiorly (C). Deep capillary plexus is affected more compared with the superficial plexus because radiation is delivered from the scleral side in plaque radiotherapy producing more severe damage in the choroid and outer retina.

sector scatter laser photocoagulation at the first sign of retinopathy, proliferative or nonproliferative.<sup>24</sup> With plaque brachytherapy, an area of ischemia develops in and 2–3 mm surrounding the location of the plaque. Treating this area and any further areas of intraretinal microangiopathy or neovascularization with scatter laser photocoagulation caused regression of retinopathy in 64% of eyes. In the same study, a subset of eyes were treated prophylactically with scatter laser photocoagulation without clinical evidence of RR, and none lost more than three lines of vision at final follow-up.<sup>24</sup> Materin et al. similarly used prophylactic circumferential sector laser photocoagulation and sub-Tenon's membrane triamcinolone injection in eyes with choroidal melanoma managed by plaque radiotherapy and concluded that this treatment combination was safe and effective to decrease the occurrence of RM.<sup>25</sup>

### Intravitreal Anti-Vascular Endothelial Growth Factor Agents

Uveal melanomas produce high levels of vascular endothelial growth factor (VEGF) in vitreous and humor aqueous and that larger tumors are associated with higher levels of VEGF.<sup>26</sup> Therefore, trace macular edema may even be present before treatment. Several small case series and retrospective

reports examined the use of intravitreal bevacizumab (anti-VEGF agent) in the treatment of RM utilizing time-domain OCT (TD-OCT). Many of these studies demonstrated a reduction in macular edema following intravitreal bevacizumab.<sup>27</sup> However, sustained decrease in macular edema often required multiple injections, and visual acuity was not found to improve significantly. More recent studies concentrated on early SD-OCT diagnosis and prompt treatment of RM. In one such report, 50% of the patients had stable or improved vision at 3 years with repeated intravitreal anti-VEGF treatment.<sup>28</sup> As a further step, Shah et al. studied the prophylactic effect of anti-VEGF therapy on RM. Those authors reported that patients receiving intravitreal bevacizumab injections every 4 months (a total of 7 injections) after plaque radiotherapy for uveal melanoma demonstrated OCT-evident macular edema and vision loss less frequently at the end of 2 years compared with controls who did not receive treatment.<sup>29</sup> This study showed that prophylactic periodic anti-VEGF therapy leads to long-term stabilization of radiation vasculopathy. Other anti-VEGF agents, including ranibizumab and aflibercept, can also be used for the treatment of RM. Finger et al. found that continuous anti-VEGF therapy with either bevacizumab or ranibizumab was well-tolerated with no RPE atrophy and preserved vision in 80% of patients with RM over a 10-year period.<sup>30</sup> The situation may be similar to exudative age-related macular degeneration where continuous

**Fig. 6.26.5** Medium-sized choroidal melanoma at the inferotemporal equator of the left eye (A) before treatment. After plaque radiotherapy (B), the melanoma has regressed and radiation maculopathy with nerve fiber layer infarcts in the macular region is noted. Sector panretinal photocoagulation was performed for proliferative radiation retinopathy, leaving minimal vitreous hemorrhage near the melanoma scar.

fixed-interval dosing of intravitreal anti-VEGF therapy seems to provide better vision stabilization or improvement status compared to as-needed regimens.<sup>31</sup> Finger et al. also pointed out that higher doses of anti-VEGF (2.5 mg versus 1.25 mg for bevacizumab and 2.0 mg versus 0.5 mg for ranibizumab) and shorter injection intervals may be used in refractory RM cases.<sup>30</sup> Tachyphylaxis or resistance to one anti-VEGF agent after an initial responsive phase may occur and requires switching to another anti-VEGF agent. Intravitreal anti-VEGF therapy also appears effective in reducing radiation-related neovascularization and vitreous hemorrhage in addition to RM, and therefore it may have a disease-modifying activity in these circumstances.<sup>32</sup>

### Corticosteroids

Triamcinolone acetonide is thought to downregulate various cytokines and decrease capillary permeability. It is used to treat macular edema secondary to various retinal pathologies and has similarly been used to treat RM. One study found that intravitreal triamcinolone acetonide (4 mg/0.1 mL) does transiently reduce macular edema and improve visual acuity.<sup>33</sup> A randomized controlled trial assessed the efficacy of periocular triamcinolone (40 mg) given at the time of plaque application, 4 months and 8 months later in preventing radiation maculopathy.<sup>34</sup> At the 18-month follow-up, eyes treated with periocular triamcinolone demonstrated less evidence of macular edema on OCT and less vision loss compared with the control group. The study reported similar rates of elevated intraocular pressure and cataract progression between the two groups.<sup>34</sup> Patients with severe, massive cystoid edema that prove to be refractory to three sequential injections of anti-VEGF agents may also benefit from consolidation with intravitreal triamcinolone.<sup>35</sup> Although triamcinolone may decrease macular edema, permanent inner segment ellipsoid band changes may limit visual recovery. Use of intravitreal dexamethasone implant has also been reported in RM.<sup>36</sup>

### Other Treatments

There are case reports of successful treatment of RR using photodynamic therapy as well as hyperbaric oxygen and oral pentoxifylline.<sup>37–39</sup> Advanced PRR complicated by vitreous hemorrhage and/or tractional retinal detachment may require pars plana vitrectomy for removing blood and reattaching the retina.<sup>40</sup>

### Prognosis

Mild NPRR, characterized by subtle capillary dropout and occasional microaneurysms may not significantly affect vision and could remain

stable for years. Patients with advanced RM and PRR can present with markedly decreased vision. In the COMS, it was estimated that 43% of patients would have a visual acuity of 20/200 or less 3 years after plaque radiotherapy.<sup>41</sup> In an analysis of 1106 eyes with uveal melanoma treated with plaque radiotherapy, Shields et al. found loss of visual acuity ( $\geq 5$  Snellen lines) in 33% of eyes at 5 years and 69% at 10 years.<sup>42</sup> A later analysis by the same group for 354 large melanomas (tumor thickness  $> 8$  mm), revealed visual acuity of 20/200 or worse in 57% of the eyes by 5 years and 89% by 10 years.<sup>43</sup>

## RADIATION PAPILLOPATHY

Radiation papillopathy (RP) or radiation optic neuropathy, similar to RR, may be seen after both brachytherapy and teletherapy. Interestingly, almost all patients who suffer from acute RP have accompanying RR, especially RM.

### Pathology and Pathogenesis

Radiation injury includes both vascular and neuropathic effects.<sup>4</sup> The creation of radiation-induced free radicals affects both the vascular endothelial cells and neuroglial cells. The induction of genetic mutations in glial cells by ionizing radiation can lead to demyelination and necrotic degeneration.<sup>4</sup> Comorbidities, including diabetes mellitus, and concurrent chemotherapy are risk factors that increase the severity of disease. The dose of radiation and latent period for the development of RP are similar to those for RR. RP usually develops with optic disc doses above 60 Gy and fraction size  $> 2$  Gy.<sup>44</sup>

### Clinical Features

RP presents with disc hyperemia, disc swelling, peripapillary edema, hard exudates, hemorrhage, and nerve fiber layer infarcts in the acute phase (Figs. 6.26.6 and 6.26.7). Rarely, RP can present with a central retinal vein occlusion secondary to disc edema. Optic nerve head swelling can persist for weeks or months but eventually leads to optic atrophy. This pattern of presentation simulates an anterior ischemic optic neuropathy. However, other rare cases of radiation optic nerve damage may simulate posterior ischemic optic neuropathy. These cases present with decreased visual acuity and relatively normal appearance of the fundus in the early stages, with optic atrophy developing later. This latter presentation usually occurs after teletherapy of the eye or adjacent structures. Because the optic nerve is confined within the scleral canal and dura, RP-associated exudative

**Fig. 6.26.6** Radiation papillopathy following plaque radiotherapy for choroidal melanoma showing disc edema, telangiectasia, and hemorrhage. Note the adjacent retinopathy with vascular thinning and dilation along the superotemporal vessels.

vasculopathy and edema occur within a confined space and lead to a visually devastating course. Some cases of RP may be associated with disc neovascularization that apparently arises from regional ischemia.<sup>45</sup>

## Diagnostic Studies

FA demonstrates that the optic disc and surrounding retinal areas are hypofluorescent in the early phase. In the late phase, there is usually leakage over the optic nerve. These findings can be explained on the basis of vascular incompetence leading to capillary closure and leakage. Preliminary data show that OCT can be used in the diagnosis and follow-up of patients with RP with features of optic disc swelling, increased optic disc thickness, and decreased peripapillary retinal thickness.<sup>46</sup> OCTA may show abnormal vessels on the optic disc. Decreased amplitudes and increased latency can be seen on flash visual evoked potential testing.

## Differential Diagnosis

RP should be differentiated from all causes of optic nerve swelling including nonarteritic optic neuropathy, arteritic (giant cell) optic neuropathy, optic neuritis, tumor invasion of the optic nerve, and papilledema.

## Treatment

There is no proven effective treatment for RP. It is usually managed with only observation. In rare cases, oral corticosteroids may be helpful to decrease pain and degree of visual loss resulting from RP. Shields et al. used intravitreal injection of 4 mg/1 mL triamcinolone acetonide, given 4 months apart, to treat acute RP.<sup>47</sup> Those authors concluded that intravitreal triamcinolone acetonide was effective in the short term to save and, in some cases, modestly improve vision. Finger and Chin reported that intravitreal injections of bevacizumab (1.25 mg/0.05 mL) given every 6–8 weeks lead to improved vision and reduced hemorrhage and disc edema in RP.<sup>45</sup>

## Prognosis

RP generally has a poor visual outcome. Vision loss is characteristically severe with hand motions to no light perception. However, there are examples of spontaneous improvement in vision in some cases.<sup>48</sup>

## SUMMARY

RR and RP may develop after radiation exposure of any type and have characteristic fundusoscopic features. FA, OCT, and OCTA are currently the

**Fig. 6.26.7** Large-sized choroidal melanoma in the nasal quadrant of the right eye (A) before treatment. After plaque radiotherapy (B), the melanoma has regressed and radiation papillopathy with disc edema and hemorrhage is noted.

most helpful studies that aid in early diagnosis, treatment planning, and subsequent follow-up. For RR treatment, laser photocoagulation and intravitreal injections of anti-VEGF medications or triamcinolone acetonide are used. Prophylactic treatment before development of RR and RM leads to better prognosis for vision. Intravitreal injections of the above drugs can also be used for RP, although in most cases little benefit in visual acuity has been demonstrated.

# Proliferative Retinopathies

Jeevan R. Mathura, Jr., Srilaxmi Bearely, Lee M. Jampol

6.27

**Definition:** A heterogeneous group of disorders with preretinal and optic disc neovascularization.

## Key Features

- Retinal new blood vessels.
- Optic disc new blood vessels.

## Associated Features

- Retinal ischemia.
- Retinal capillary nonperfusion.
- Posterior segment inflammation.
- Neoplasia.
- Vitreous hemorrhage and fibrous proliferation.
- Retinal detachment.

## INTRODUCTION

Proliferative retinopathies are diseases associated with preretinal or disc neovascularization (NV).<sup>1</sup> They can be divided into two major categories (Box 6.27.1),<sup>2-6</sup> each with its own subset of hereditary disorders:

- Systemic diseases.
- Localized retinal vascular and ocular inflammatory diseases.

In this chapter, retinal angiogenesis is reviewed, after which an approach for the management of a patient who has posterior segment NV of unknown cause is suggested. Finally, specific entities with retinal NV are described.

## RETINAL ANGIOGENESIS

Evidence suggests that the orderly development and maintenance of the normal retinal vasculature requires the balance of proangiogenic and antiangiogenic factors. Ischemia, inflammation, or neoplasia may upset this balance, resulting in pathological new blood vessel formation (Fig. 6.27.1).<sup>7</sup> Posterior segment NV involves the local upregulation of proangiogenic cytokines.

Animal studies have demonstrated that upregulated vascular endothelial growth factor (VEGF) is an important stimulant for pathological ocular NV. In experimental models, increased expression of VEGF stimulates NV, whereas antagonists of VEGF signaling inhibit NV.<sup>8</sup>

VEGF has been shown to be upregulated by hypoxia. Hypoxia-inducible factor (HIF) is a promoter for VEGF. Hypoxia suppresses ubiquitination of HIF1 $\alpha$ , which results in increased levels of VEGF.<sup>9</sup> Levels of VEGF are elevated in the retina and vitreous of patients and animals with ischemic retinopathies.<sup>10</sup> VEGF antagonists, such as bevacizumab<sup>11</sup> and ranibizumab,<sup>12</sup> have been shown to cause regression of new vessels. Aflibercept, an antagonist of VEGF and placental growth factor (PGF), is being investigated and now widely used for this indication.<sup>13</sup> This potentially could demonstrate increased efficacy as PGF may be important in the development of proliferative retinopathies.<sup>14</sup>

NV has the potential to cause loss of vision because the new vessels are fragile and rupture easily. Patients may develop vitreous hemorrhage, fibrovascular scarring, epiretinal membranes (ERMs), and retinal traction, which can lead to both rhegmatogenous and tractional retinal detachments (TRDs). Early detection of NV and appropriate treatment may minimize the risks of these complications.

## BOX 6.27.1 Retinal Neovascularization

### Systemic Diseases

- Diabetes mellitus
- Hyperviscosity syndromes
- Aortic arch syndromes and ocular ischemic syndromes
- Carotid-cavernous fistula
- Multiple sclerosis
- Retinal vasculitis
- Systemic lupus erythematosus
- Arteriolitis with SS-A autoantibody
- Acute multifocal hemorrhagic vasculitis
- Vasculitis resulting from infection
- Vasculitis resulting from Behçet's disease
- Sarcoidosis
- Coagulopathies

### Systemic Diseases With a Strong Hereditary Component

- Sickling hemoglobinopathies
- SC, SS, S $\beta$ -thalassemia, SO Arab
- Other hemoglobinopathies
- AC and C- $\beta$  thalassemia
- Small-vessel hyalinosis
- Incontinentia pigmenti
- Familial telangiectasia, spondyloepiphyseal dysplasia, hypothyroidism, neovascularization, and tractional retinal detachment

### Retinal Vascular and Ocular Inflammatory Diseases

- Eales' disease
- Retinal artery or vein occlusion
- Frosted branch angiitis<sup>2</sup>
- Idiopathic retinal vasculitis, aneurysms, and neuroretinitis<sup>3</sup>
- Retinal embolization (e.g., talc)
- Retinopathy of prematurity
- Encircling buckling operation
- Uveitis, including pars planitis
- Acute retinal necrosis
- Birdshot retinochoroidopathy
- Long-standing retinal detachment
- Choroidal melanoma, choroidal hemangioma
- Cocaine abuse
- Optic nerve aplasia,<sup>4</sup> myelinated nerve fiber layer<sup>5</sup>
- Radiation retinopathy<sup>6</sup>

### Retinal Diseases With a Strong Hereditary Component

- Familial exudative vitreoretinopathy
- Inherited retinal venous beading
- Retinoschisis
- Retinitis pigmentosa
- Autosomal dominant vitreoretinopathies

## OVERVIEW OF DIAGNOSING NEOVASCULARIZATION

If the cause of retinal NV is unknown, the physician should obtain a detailed medical, family, birth, and social histories. Diabetes, retinopathy of prematurity (ROP), talc retinopathy, and familial (autosomal dominant, recessive, or X-linked) exudative vitreoretinopathy (FEVR) all are diagnoses that a thorough history will help to uncover. Furthermore, with a detailed review of systems and a family history, disorders can be grouped quickly

**Fig. 6.27.1 Sequence of Events in Angiogenesis.**

Ischemic tissue makes and releases angiogenic factors, which bind to specific receptors on vascular endothelial cells (ECs). This binding activates the ECs, which then proliferate and directionally migrate through remodeled extracellular matrix. These migrating ECs form tubes and then loops, which eventually become stabilized by smooth muscle cells and pericytes.

into one of the categories outlined in [Box 6.27.1](#). Finally, laboratory tests can be directed toward specific disorders suggested by the history and examination. For example, a suspected diagnosis of a hemoglobinopathy may be confirmed by hemoglobin electrophoresis.

Retinal NV can be visualized during ophthalmoscopy and on fundus photography as new vessels above the surface of the retina. In addition to imaging TRDs and ERMs, optical coherence tomography (OCT) can detect retinal NV seen as abnormal tissue in the vitreous, attached to the retina or optic nerve.<sup>15</sup> Fluorescein angiography (FA) is helpful not only for identifying retinal NV but also for delineating areas of ischemia as indicated by capillary nonperfusion. OCT angiography (OCTA) can detect flow in preretinal and optic disc NV and also areas of capillary nonperfusion.<sup>16</sup> This can be performed without the intravenous dye injection needed for FA; however, a smaller field is visualized.

## OVERVIEW OF TREATING NEOVASCULARIZATION

Treatment is given to prevent complications, such as vitreous hemorrhage and retinal detachment. In addition to treatment of the underlying systemic condition, the neovascular tissue itself should be treated by photocoagulation, anti-VEGF therapy, anti-inflammatory therapy, cryotherapy, or vitreoretinal surgery, alone or in combination.

The rationale of treatment is to alter ischemic or inflammatory tissues so that the neovascular stimulus is suppressed,<sup>17</sup> this is usually accomplished by laser in the range of 532–577 nm to create retinal burns. In general, laser spots are scattered about 1–2 burn-widths apart in areas of the retina thought to be ischemic. The power and duration settings on the laser are adjusted so that the laser burn appears as a moderate-intensity, gray-white lesion.

If the retinal ischemic process seems to affect the entire retina diffusely, such as in diabetes mellitus, scatter photocoagulation should be placed throughout the peripheral retina (panretinal photocoagulation). Local scatter laser directed to areas of capillary nonperfusion is indicated for some conditions, such as sickle cell retinopathy,<sup>18</sup> incontinentia pigmenti,<sup>19</sup> retinal vein occlusion,<sup>20</sup> and ROP.<sup>21</sup> Direct treatment of vessels flat on the retina that feed or drain neovascular tissue (feeder-vessel coagulation) is effective. However, such treatment has a greater incidence of complications, which include retinal tears or breaks in Bruch's membrane,

compared with scatter treatment. Direct treatment of elevated neovascular tissue is not effective.

When hemorrhages or dense cataracts are present, red or diode laser may be used because these wavelengths penetrate such media better, or the cataract may be removed.

Cryotherapy may be useful if neovascular tissue cannot be treated with laser (e.g., because of a media opacity or the treatment area is very anterior). Similar to the laser, it is applied to peripheral ischemic retina and affects the neovascular tissue indirectly. Alternatively, vitreoretinal surgery is indicated for long-standing vitreous hemorrhage, for repair of rhegmatogenous or tractional retinal detachment, and when epiretinal membrane removal is needed. Removal of the posterior vitreous face also removes the scaffolding for further NV. Furthermore, vitrectomy may remove angiogenic factors affecting the retinal vasculature.

The use of intravitreal injections of anti-VEGF is efficacious, alone or in combination with other modalities, especially if media opacity is present. Treatment with anti-VEGF alone, however, may require visits for injections up to every 4 weeks.<sup>12</sup>

Anti-VEGF treatment has been shown to be efficacious for pediatric proliferative retinal diseases and may require only one injection, but these indications are not standard of care at this time.<sup>22–24</sup>

## ENTITIES ASSOCIATED WITH RETINAL NEOVASCULARIZATION

### Systemic Diseases

#### Diabetes Mellitus

The vast majority of NV from diabetes occurs posterior to the equator ([Fig. 6.27.2](#)). A program of tight blood sugar control helps to prevent the development of neovascularization. (For a more detailed description of diabetic retinopathy, see Chapter 6.22.)

#### Hyperviscosity Syndromes

Patients with certain diseases, such as chronic myelogenous leukemia,<sup>25</sup> essential thrombocytosis, or polycythemia vera, may exhibit dramatic elevations in their leukocyte, platelet, or red blood cell counts, respectively. These elevations increase blood viscosity, which may produce sludging of blood in the peripheral retina. The consequences of this abnormal flow

**Fig. 6.27.2 Diabetes Mellitus.** Large areas of retinal neovascularization seen in a patient who has long-standing insulin-dependent diabetes mellitus.

include venular dilation, perivenous sheathing, capillary dropout, and microaneurysm formation. NV develops at the border of perfused and nonperfused retina.<sup>26</sup>

### Aortic Arch Syndromes and Ocular Ischemic Syndromes

Patients with atherosclerosis that involves the carotid artery or aortic arch, arteritis (e.g., Takayasu's disease), or syphilitic aortic involvement may develop iris, disc, or peripheral retinal NV.<sup>27</sup> Extensive narrowing of the large arteries that supply the eye causes ischemia and subsequent NV. Although both cryotherapy and scatter photocoagulation are helpful, they are less successful in these syndromes than in others, perhaps because the vasoproliferative stimulus is so intense and diffuse within the eye (see Chapter 6.23). Interventions, such as carotid endarterectomy, may improve perfusion to the retina resulting in regression of the neovascularization.<sup>28</sup>

### Carotid–Cavernous Fistula

In a carotid–cavernous fistula, carotid arterial blood enters the cavernous sinus venous system directly, bypassing the eye, and consequent ischemia may stimulate retinal NV.<sup>29</sup>

### Multiple Sclerosis

Patients with multiple sclerosis may develop uveitis, peripheral retinal venous inflammatory sheathing (Rucker's sign), or arteriolar sheathing, which occurs less frequently. If the vasculitis affects perfusion, ischemia and NV may ensue.<sup>30</sup>

### Retinal Vasculitis

NV may result from ocular inflammation. The neovascular signal may be from ischemia, as blood flow is impaired, or induced by the inflammatory response. Specific vasculitic entities that cause retinal neovascularization include systemic lupus erythematosus (SLE),<sup>31</sup> arteriolitis with SS-A autoantibody, acute multifocal hemorrhagic vasculitis, and vasculitis that occurs with infection (e.g., herpesviruses, *Toxoplasma*, and cytomegalovirus<sup>32</sup>).

In SLE, vascular proliferation may occur despite normal antinuclear antibody (ANA) or complement levels. Patients who have a constellation of findings that resemble SLE and whose blood studies are ANA negative and SS-A autoantibody positive also may develop proliferative changes. Patients affected by acute multifocal hemorrhagic vasculitis have decreased visual acuity, retinal hemorrhages, posterior retinal infiltrates, vitritis, and papillitis, and they also may develop retinal NV.<sup>33</sup> Treatment of the underlying vasculitis with anti-inflammatory agents or immune suppression may be beneficial.

### Sarcoidosis

Sarcoidosis is an idiopathic granulomatous disorder that affects multiple organ systems. The ocular manifestations are disparate and include uveitis with periphlebitis. Inflammation may stimulate NV either by the direct liberation of an angiogenic stimulus or indirectly by blocking blood flow, which results in ischemia.<sup>34</sup>

**Fig. 6.27.3 Incontinentia Pigmenti.** The peripheral retina of a patient who has incontinentia pigmenti demonstrates somewhat elevated vessels with white vessel walls. The majority of these vessels show nonperfusion. The more posterior retina was perfused, and the anterior retina was ischemic.

## Systemic Diseases That Have a Strong Hereditary Component

### Hemoglobinopathies

In sickling hemoglobinopathies, erythrocytes can assume the shape of an elongated crescent or sickle. Point mutations result in amino acid substitutions within the hemoglobin molecule that change its tertiary structure under conditions of low oxygen tension, acidosis, or hypercapnia. These abnormally shaped erythrocytes become trapped in precapillary arterioles or capillaries and disrupt circulation. Common tissues affected are those of the spleen, bones, lungs, and eyes. These diseases are highly prevalent among people of Mediterranean, African, Indian, and Saudi Arabian ancestries.

Sickling of erythrocytes and changes of the vascular endothelium in the retinal periphery result in capillary nonperfusion. Ischemic signals lead to peripheral NV that takes the shape of a sea fan, a type of coral.<sup>35</sup> Although the term *sea fan* is associated with sickle cell retinopathy most commonly, almost any type of peripheral retinal NV may assume this configuration. Investigations of angiogenic factors in proliferative sickle cell retinopathy have demonstrated VEGF and basic fibroblast growth factor to be associated with sea fan formations.<sup>36</sup>

The likelihood of NV depends on the type of hemoglobinopathy. For example, patients who have hemoglobin SC disease are 10 times more likely to develop peripheral NV compared with patients affected by hemoglobin SS disease. This difference may be partly secondary to the higher hematocrit and blood viscosity in hemoglobin SC disease.

Loss of vision can occur if fragile neovascular tissue hemorrhages into the vitreous. With repeated hemorrhages and vitreous degeneration, fibrovascular elements of the vitreous may exert traction on the retina, and tractional or rhegmatogenous retinal detachment may ensue. Fibrovascular proliferation or nonvascular epiretinal membranes that affect the macula can degrade vision by the formation of macular pucker or macular holes. Hemoglobinopathies other than sickle cell disease, such as AC and C- $\beta$  thalassemia, rarely may cause peripheral retinal NV.

### Incontinentia Pigmenti

Incontinentia pigmenti is a rare X-linked dominant disorder that tends to be lethal for male fetuses in utero, so nearly all affected patients are female. Patients have dermatological, neurological, dental, and ophthalmological findings.

One third of patients with incontinentia pigmenti have ophthalmological findings, including cataracts, strabismus, optic atrophy, and foveal hypoplasia. The peripheral retinal vasculature often is poorly developed (Fig. 6.27.3), and at the junction of normal and abnormal vasculature, arteriovenous anastomoses, microvascular anomalies, and neovascularization may develop.<sup>37</sup> Vitreous hemorrhage, retinal tears, and retinal detachment may ensue. Although a predilection for peripheral involvement of

vascular changes is well established, the posterior pole can be affected by similar findings. NV has been treated effectively in some cases by using cryopexy or laser.

## Retinal Vascular and Ocular Inflammatory Diseases

### Eales' Disease

Strictly defined, Eales' disease is an exclusively bilateral disorder of young (20–45 years old), otherwise healthy adults most commonly noted in developing countries (especially India). These patients have periphlebitis and develop peripheral retinal capillary nonperfusion, often superotemporally. The etiology remains unknown. Hypersensitivity to tuberculin protein has been reported; however, no clear relationship to tuberculosis has been found. The designation of Eales' disease sometimes is used for any patient who has peripheral NV and no clinical or laboratory features that identify another specific entity.

The principle that neovascularization occurs at the border of perfused and nonperfused retina applies to Eales' disease.<sup>38</sup> Scatter photocoagulation of ischemic retina has been shown to cause regression of neovascular tissue, presumably by a modulation of the ischemic signal for NV. Direct feeder-vessel treatment also has been used. The phlebitis responds to systemic or ocular corticosteroid therapy. Overall, the visual prognosis in Eales' disease is good, although patients may develop complications, such as vitreous hemorrhage, tractional or rhegmatogenous retinal detachment, rubeosis irides, secondary glaucoma, or cataract.

### Retinal Vein Occlusion

Retinal neovascularization can occur with branch retinal vein occlusion.<sup>39</sup> Complications include vitreous hemorrhage, epiretinal membranes, and tractional or rhegmatogenous retinal detachments (see Chapter 6.20: Venous Occlusive Disease of the Retina).

### Retinal Embolization

Drug abusers who intravenously inject chopped pills that contain talc may develop retinal NV.<sup>40</sup> The talc reaches the ocular arterial system after passage through capillaries or collaterals in the pulmonary vascular system. The talc wedges in smaller-caliber arterioles, such as those found in the macula and retinal periphery. Ischemia and neovascularization may ensue (Fig. 6.274).

### Retinopathy of Prematurity

ROP affects the peripheral vasculature of the retina. Normal vascularization of the retina commences at 4 months' gestation and usually is completed by 9 months. In some instances of low birth weight, prematurity, and supplemental administration of oxygen, the normal process of vascularization is interrupted. How this occurs is poorly understood, but it is

**Fig. 6.274 Talc Retinopathy.** An area of sea fan neovascularization with a small overlying vitreous hemorrhage is shown in an intravenous drug abuser. Talc retinopathy is demonstrated elsewhere in the fundus.

thought that hyperoxia from supplemental oxygen may further interrupt normal vascular development and that hypoxia associated with maturing avascular retina may result in liberation of angiogenic stimuli. Some infants progress to NV and its complications, which include tractional, exudative, or rhegmatogenous retinal detachment (see Chapter 6.21: Retinopathy of Prematurity).<sup>41</sup>

The presence of risk factors for ROP must trigger careful examination and follow-up. Treatment helps preserve an attached macula (see Chapter 6.21).

### Uveitis

Some patients with uveitis, especially intermediate uveitis and pars planitis, develop NV of the disc or peripheral retina. Uveitic NV appears to be determined by the severity of inflammation and presence of retinal nonperfusion (see Part 7: Uveitis and Other Intraocular Inflammations).<sup>42</sup>

### Acute Retinal Necrosis

Both herpes simplex and herpes zoster cause the acute retinal necrosis syndrome, with findings that include anterior uveitis, vitritis, retinal vasculitis, necrotizing retinitis, and retinal detachment. The inflammation and ischemia may stimulate vascular proliferation (see Part 7: Uveitis and Other Intraocular Inflammations).<sup>43</sup>

### Birdshot Chorioretinopathy

Birdshot chorioretinopathy is characterized by white lesions in the choroid, and by vitritis, papillitis, and macular edema. Closure of peripheral retinal vessels may lead to vasoproliferation (see Part 7: Uveitis and Other Intraocular Inflammations).<sup>44</sup>

### Long-Standing Retinal Detachment

Retinal ischemia in a patient who has a prolonged retinal detachment may result from disruption of either the retinal or choroidal supply of oxygen or nutrients to the retina. The NV may appear angiomatous or may take the shape of a sea fan. Surgical repair of a rhegmatogenous detachment can cause regression of the neovascularization.<sup>45</sup>

### Choroidal Melanoma and Hemangioma

Choroidal melanoma<sup>46</sup> and hemangioma,<sup>47</sup> perhaps by the release of a tumor angiogenic factor or secondary to retinal detachment over the tumor, can promote neovascularization that overlies the tumor. Treatment of a choroidal melanoma with radiation or scatter photocoagulation can cause regression of the neovascularization. (Ocular tumors are covered in Part 8.)

## Hereditary Retinal Diseases

### Familial Exudative Vitreoretinopathy

FEVR is a group of vascular disorders of the peripheral retina with findings on retinal examination that are very similar to those of ROP. However, FEVR differs from ROP in that patients usually are born at full term, have normal birth weight, and have not had supplemental oxygenation. In addition, a positive family history often is found. A demarcation line that separates vascular retina from avascular retina may occur in the retinal periphery. Peripheral retinal vessels assume a characteristic straightened course.

Presumably, an ischemic signal from the avascular retina stimulates NV. These vessels may leak, form intraretinal or subretinal exudates, and result in exudative retinal detachment. Some eyes develop cicatricial changes, which include straightened retinal vessels, foveal ectopia, meridional folds, or tractional or rhegmatogenous retinal detachment. Other complications include cataract, band keratopathy, rubeosis iridis, neovascular glaucoma and, in some eyes, phthisis bulbi.<sup>48</sup> As in ROP, treatment depends on early recognition.

### Inherited Retinal Venous Beading

This rare entity has an autosomal dominant inheritance pattern. Findings include venous beading, microaneurysms, hemorrhages, exudates, NV, and vitreous hemorrhage.<sup>49</sup>

### Retinoschisis

Patients who have X-linked (juvenile) retinoschisis, degenerative retinoschisis, or acquired retinoschisis with shaken baby syndrome<sup>50</sup> can develop retinal NV. In X-linked retinoschisis, whitish deposits may be seen at the point where peripheral vessels appear to be occluded. Consequent to vascular occlusion, ischemia may promote NV.<sup>51</sup>

**Fig. 6.27.5 Retinitis Pigmentosa.** This fundus view demonstrates neovascularization of the disc, neovascularization elsewhere, and a small vitreous hemorrhage in a patient who has autosomal dominant retinitis pigmentosa.

### Retinitis Pigmentosa

Patients with retinitis pigmentosa can have neovascularization of the disc and retina (Fig. 6.27.5).<sup>52</sup> The pathogenesis of the NV is unknown but may be related to the inflammation seen in this disorder. These patients have diffuse loss of retinal pigment epithelial cells, so laser photocoagulation burns are difficult to create. Treatment of the neovascularization may not

be necessary in these patients as it may spontaneously regress (see Chapter 6.14: Progressive and “Stationary” Inherited Retinal Degenerations).

### Autosomal Dominant Vitreoretinopathy

Autosomal dominant vitreoretinopathy is a rare disorder that manifests as abnormal peripheral chorioretinal pigmentation with a characteristic sharp demarcation near the equator. Patients also may manifest cataract, macular edema, retinal NV, vitreous hemorrhage, and selective b-wave reduction on electroretinography.<sup>53</sup> This entity has been shown to be caused by specific mutations in the BEST1 gene.<sup>54</sup>

## Retinal Arterial Macroaneurysms

6.28

Ivy Zhu, William F. Mieler, Clement C. Chow

**Definition:** Localized fusiform or saccular dilatation of a retinal arterial vessel within the first three orders of bifurcation.

**Key Features**

- Retinal hemorrhage (subretinal, intraretinal, preretinal, and vitreous).
- Macular edema and lipid exudation.

**Associated Features**

- Leaking, telangiectatic vessels in the capillary bed that surrounds the macroaneurysm.
- May be associated with occlusion of retinal artery or vein.

**INTRODUCTION**

Although aneurysms of the retinal arteries have been noted since the early 1900s, Robertson in 1973 was the first to coin the term “macroaneurysm” to describe a distinct clinical entity that consisted of an acquired focal dilatation of a retinal artery within the first three orders of bifurcation.<sup>1</sup> Macroaneurysms are saccular or fusiform in shape and vary from 100–250 microns in diameter; this differentiates them readily from capillary microaneurysms, which are usually <100 microns in diameter. Retinal arterial macroaneurysms (RAMs) can be further differentiated from the vessel dilatations seen in Coats’ disease, in which multiple saccular outpouchings of predominantly the venous and capillary systems are associated with congenital retinal telangiectasias and lipid exudation and primarily found in young males.

RAMs typically arise, enlarge, and then eventually thrombose, fibrose, and involute. Although the clinical course is most often benign, significant visual morbidity may result from macular hemorrhage, exudate, or edema, or from the development of a vitreous hemorrhage. Thus a typical categorization of RAMs, first provided by Lavin et al., is (1) hemorrhagic—where hemorrhage is the dominant finding, measures >1 disc diameter, and causes loss of visual acuity; (2) exudative—where exudates are the dominant finding, measures >1 cup diameter, and causes loss of visual acuity; and (3) quiescent—where hemorrhage and/or exudate, if it exists, spares the macula and does not lead to loss in visual acuity.<sup>2</sup>

**EPIDEMIOLOGY AND PATHOGENESIS**

The prevalence of RAMs ranges from 0.01% to 0.07%.<sup>3,4</sup> Most patients with RAMs are over age 60 years,<sup>5–9</sup> and RAMs occur predominantly in females (60%–100%).<sup>5–10</sup> Macroaneurysms typically present in one eye, with bilaterality in <10%.<sup>11</sup> The most consistent association is with systemic hypertension—a large controlled study reported it in 79% of patients with RAMs.<sup>9</sup> Less commonly, RAMs may be part of a known syndrome, such as idiopathic retinal vasculitis, aneurysms, and neuroretinitis (IRVAN) syndrome, or inherited as seen in familial retinal arterial macroaneurysms (FRAMs).<sup>12–14</sup>

The exact pathogenesis of a macroaneurysm is unknown, but several theories exist. Some compare RAMs to cerebral arterial aneurysms, which are generally 100–300 microns in diameter, are also more common in women, and occur in patients age >50 years with a history of hypertension.<sup>1,2,15</sup> Chronic hypertension, along with the replacement of arterial smooth muscle by collagen in aging, may effect a focal dilatation of the arterial wall in an area of weakness or prior damage. Lavin et al. postulated that macroaneurysms are detected more frequently at arteriovenous

crossings because at these locations the arterial and venous walls are in contact without an adventitial layer, which results in an area of limited structural support.<sup>2</sup> Other investigators have noted the development of macroaneurysms at the sites of previously detected emboli.<sup>7,16</sup> They hypothesized that focal arterial damage secondary to embolization can lead to aneurysm formation. However, Gass proposed that the focal, yellow arterial plaques, often present at these sites of previously reported emboli, are most likely atheromas.<sup>17</sup>

There may be differences between the RAMs that lead to hemorrhagic complications and those that result in lipid exudation.<sup>8</sup> Saccular or “blowout” aneurysms are more prone to bleed, possibly as a result of a thin, stretched aneurysmal sac. These develop closer to the optic nerve head, where perfusion pressures are higher.<sup>2</sup> Additionally, systolic blood pressures above 200 mm Hg are more common in patients who have bleeding macroaneurysms. Fusiform dilatations, however, are more prone to exudation and to be associated with venous occlusions.<sup>2,8</sup> It is also possible that the cause of those aneurysms that eventually lead to hemorrhagic complications is more dependent on hypertension and vessel wall damage, while the cause of those that lead to exudation is more contingent on local vascular factors.

**OCULAR MANIFESTATIONS**

Hemorrhagic macroaneurysms can result in acute loss of vision with evidence of subretinal, intraretinal, or preretinal hemorrhage on ocular examination (Fig. 6.28.1). Subretinal hemorrhage may be toxic to the retina, and fibrin clot retraction in the submacular space can lead to permanent structural change, affecting central vision. Often the hemorrhage obscures the site of the aneurysm, but the presence of a localized preretinal and subretinal hemorrhage over a major retinal artery should suggest the possibility of its presence. A nonclearing vitreous hemorrhage without evidence of retinal tear or posterior vitreous detachment may be the result of a macroaneurysm. Because bleeding tends to thrombose the aneurysm, once the hemorrhage has cleared, detection may be difficult. The involved artery often retains a focal tortuosity or “Z”-shaped kink at the location of the

**Fig. 6.28.1 Hemorrhagic Macroaneurysm.** Surrounding hemorrhage in the retinal and subretinal space surrounding the artery.

**Fig. 6.28.2 Exudative Macroaneurysm.** Note the extensive leakage from the macroaneurysm located along the superotemporal arcade, with marked lipid exudation that extends into the central macula

previously ruptured aneurysm, which lends indirect evidence in support of the diagnosis.

Patients may present with a more gradual decline in vision secondary to serous fluid and lipid accumulation in the macula (Fig. 6.28.2). Exudative macroaneurysms are most often located on the temporal vascular arcades. In one series, 94.7% of macroaneurysms were in the temporal retina, with an equal distribution between superotemporal and inferotemporal locations.<sup>18</sup> Rarely, macroaneurysms may occur on the optic nerve head, cilio-retinal artery, and nasal vessels.<sup>19,20</sup> They frequently demonstrate a circinate lipid pattern (see Fig. 6.28.2).

Macroaneurysms discovered on routine examination may have only a small (or absent) cuff of hemorrhage and lipid exudation associated with them. Up to 10% of macroaneurysms may be pulsatile on presentation; although some investigators maintain that this shortly precedes rupture, most believe it is of no prognostic significance.<sup>11</sup> Marked, chronic foveal exudate can cause structural and permanent changes and may therefore indicate poor visual outcomes.

Macroaneurysms may be associated with retinal vein occlusions, often in the artery that serves the vascular territory of the occluded vein.<sup>9</sup> Distal arterial narrowing and arterial occlusion of the involved vessel are common and have been reported to occur in 26% and 8% of cases, respectively.<sup>9</sup> Macular hole formation after macroaneurysm rupture has also been reported.<sup>21–23</sup> In addition, one report documents the development of retinal macroaneurysms in a 62-year-old patient who had a history of congenital arteriovenous communications.<sup>24</sup>

## DIAGNOSIS AND ANCILLARY TESTING

Fluorescein angiography (FA) may reveal the macroaneurysm, usually demonstrating immediate, complete filling of the aneurysm (Fig. 6.28.3). In some cases, irregular and incomplete filling may be associated with partial thrombosis, and a faint shell of fluorescence may be displayed with a completely involuted macroaneurysm.<sup>11</sup> Leakage from the wall of the aneurysm is common in active lesions. Evidence of arteriolar narrowing usually is present proximal and distal to the macroaneurysm.<sup>16</sup> In many cases, microvascular abnormalities surround the aneurysm, including a wider capillary-free zone, capillary dilatation, capillary nonperfusion, microaneurysms, and intra-arterial collateral vessels<sup>16,18</sup> (Fig. 6.28.4).

In cases with dense hemorrhage where FA does not provide definitive evidence of a RAM, indocyanine green angiography (ICGA) can be a useful adjunct.<sup>25</sup> Because the absorption and emission spectra are in the near-infrared range, the dye can better penetrate through dense hemorrhages, revealing structures that may otherwise be obscured. Additionally, in treatment of a macroaneurysm, the ICG dye may leak less than fluorescein, thus providing well-defined images.<sup>25</sup>

There has been an increase in the role of optical coherence tomography (OCT) in the assessment and treatment of RAMs. Traditionally, it has been used to assess for the presence of macular edema and serous detachment, as well as to monitor response to treatment.<sup>26</sup> In eyes with untreated, active RAMs, OCT shows a round inner retinal lesion, which has a thick

**Fig. 6.28.3 Hemorrhagic Macroaneurysm.** Fluorescein angiography demonstrating complete early filling of the macroaneurysm with fluorescein dye, and surrounding blockage from the hemorrhage.

hyperreflective wall with a dark lumen<sup>27</sup> (Fig. 6.28.5). After laser photocoagulation, OCT shows hyperreflectivity in the lumen of the macroaneurysms, indicating thrombus formation.<sup>27</sup> Superficial retinal hemorrhage, intraretinal lipids, and intraretinal edema predominantly involving the outer retinal layers can also be seen associated with macroaneurysms.<sup>27,28</sup>

OCTA may provide a noninvasive alternative for high-resolution visualization of these lesions before and after laser treatment. In a case series of three patients with RAMs, OCTA (with or without traditional OCT) was able to localize the depth of the lesion and provide dynamic information on blood flow in different retinal layers.<sup>29</sup>

## DIFFERENTIAL DIAGNOSIS

Large-capillary aneurysms secondary to retinal venous obstruction may simulate RAMs.<sup>30,31</sup> In the Branch Vein Occlusion Study,<sup>32</sup> four types of aneurysms were found in the area of the vein occlusion: arterial, capillary, venous, and associated with collaterals. Other similar-appearing conditions include:

- Retinal telangiectasia of Coats' disease<sup>10</sup> (Fig. 6.28.6).
- Capillary hemangiomas of the retina.<sup>33</sup>
- Acquired nonfamilial angiomas, along with vasoproliferative tumors.<sup>34,35</sup>
- Choroidal neovascular membrane from age-related macular degeneration (Fig. 6.28.7); IRVAN (idiopathic retinal vasculitis, aneurysms, and

**Fig. 6.28.4 Macroaneurysm With Surrounding Dilated, Telangiectatic Capillary Bed.** (A) A large bilobed macroaneurysm with surrounding circinate lipid. neuroretinitis) syndrome (Fig. 6.28.8)<sup>12,15,36,37</sup>; familial retinal artery macroaneurysms (FRAMs).<sup>13,14</sup>

## SYSTEMIC ASSOCIATIONS

The only consistent systemic association with RAMs is systemic arterial hypertension. In a case-control series, 79% of patients with macroaneurysms were found to have hypertension compared with 55% of controls—a statistically significant difference.<sup>9</sup> The evaluation of a patient with a macroaneurysm but no previous history of hypertension should include a workup for hypertension and possibly an additional cardiac workup.<sup>18</sup>

## PATHOLOGY

Gold et al. described a pathological specimen from a patient with a single macroaneurysm and a large ring of circinate lipid in the macula.<sup>38</sup> The macroaneurysm was located at an arteriovenous crossing, surrounded by dilated capillaries and a heterogeneous accumulation of collagen, hemosiderin, and lipid, with a paramacular deposition of lipid and proteinaceous exudate in the outer plexiform layer. It was proposed that the dilated capillary network surrounding the macroaneurysm was the source of serous and lipid exudation into the macula. Other reports of ruptured aneurysms have shown evidence of a break in the artery covered by a dense fibrin-platelet clot that contains blood, exudate, lipid-laden macrophages, hemosiderin, and fibroglial reaction products in amounts that vary among patients (Fig. 6.28.9).<sup>39</sup>

**Fig. 6.28.7 Macular Hemorrhage, Simulating Age-Related Macular Degeneration.** (A) Subretinal and subretinal pigment epithelium (RPE) hemorrhage in the macula and coursing inferiorly. (B) Fluorescein angiography reveals the source of the hemorrhage to be a retinal arterial macroaneurysm.

## TREATMENT, COURSE, AND OUTCOME

Hemorrhagic macroaneurysms, especially those that cause vitreous or pre-retinal hemorrhage, tend to thrombose, and ultimately, the visual outcome for patients with these macroaneurysms is better than for those with exudative macroaneurysms, which lead to development of macular edema.<sup>5,6,8,13,40</sup>

Treatments using the xenon arc,<sup>7,8</sup> argon,<sup>2,13,41</sup> and dye yellow<sup>42,44</sup> lasers, both directly at and around the macroaneurysm, have been described, although a laser approach remains controversial. Some investigators believe that patients who have exudative macroaneurysms and significant macular involvement should undergo photocoagulation treatment, either directly to the lesion<sup>7,8,43,44</sup> (Fig. 6.28.10) or to the surrounding capillary bed<sup>13,40</sup> in an effort to close the macroaneurysm and the leaking perianeurysmal vessels. The rationale is that the poorest visual outcomes are observed when macular edema and lipid are allowed to remain for many months. However, no prospective trial of laser treatment for RAMs has been performed, and the several small, uncontrolled clinical series have demonstrated mixed results. Multiple investigators have found no visual benefit to using laser therapy compared with observation, and some have even reported a greater risk for visual decrease with laser therapy.<sup>8,15,41</sup> In contrast, Joondeph et al. reported improvement in visual acuity in 8 of 12 cases with use of the dye yellow laser.<sup>44</sup> Meyer et al. reported that eyes with hemorrhagic RAMs treated with laser compared with controls had greater improvement in visual acuity, whereas there was no difference between the treatment and observation groups in eyes with exudative RAMs.<sup>45</sup> A larger case series of 49 eyes with RAMs showed comparable final visual acuity after 3 years in patients who were untreated, treated with laser, or treated surgically.<sup>46</sup> However, the authors suggested that the equivocal

(D) Fluorescein angiography shows occlusion of the superotemporal artery, although still with mild macular edema.

outcomes resulted from individualized disease management, with more severe cases undergoing more invasive treatment. Laser surgery has been associated with an increased threat of arteriolar occlusion, which theoretically may be amplified when using the dye yellow laser.<sup>9,42</sup> Other complications include enlargement of laser scar, choroidal neovascularization, and subretinal fibrosis. Subthreshold laser treatment has been proposed as an alternative to minimize the adverse effects of conventional laser by reducing the duration of laser exposure and by using a subvisible clinical endpoint.<sup>47,48</sup> In a randomized trial, Battaglia et al. compared the effects of subthreshold (810 nm infrared diode laser) and conventional laser (647 nm krypton laser) treatment in 25 patients with symptomatic RAMs associated with macular edema.<sup>47</sup> Both groups achieved similar outcomes with significantly improved visual acuity (from 20/100–20/40), resolution of macular edema, and improved OCT retinal thickness at the 1-year follow-up. Three eyes (23%) in the conventional laser group developed symptomatic epiretinal membrane, whereas the subthreshold group

had no complications. However, until definitive studies are performed to elucidate the role of laser, it should be reserved for select exudative macroaneurysms that threaten the fovea with the progressive accumulation of lipid. When employing conventional laser, argon green, or dye yellow lasers, long-duration burns (0.2–0.5 seconds) and large spot sizes (500 mm diameter) can be used. With subthreshold laser, an infrared diode laser can be used with high power (1400 mW) and short duration (0.3 seconds with duty cycle of 15%).<sup>47</sup>

Intravitreal anti-vascular endothelial growth factor (anti-VEGF) agents, including bevacizumab, ranibizumab, and aflibercept, have also been used off-label to treat macular edema and/or hemorrhages secondary to RAMs (see Fig. 6.28.10).<sup>49–53</sup> A prospective interventional case series of 37 patients showed a statistically significant improvement in visual acuity (20/80–20/25) and central subfield thickness (520–214  $\mu$ m) after 3 monthly intravitreal bevacizumab injections.<sup>53</sup> However, a retrospective case series of 23 eyes, which compared bevacizumab injection with observation,

showed no statistically significant difference in visual acuity or central macular thickness after 3 months, although more rapid improvement was noted in the treatment arm.<sup>54</sup> There are also favorable reports of the use of intravitreal ranibizumab<sup>55-57</sup> and aflibercept.<sup>58</sup> A randomized controlled trial is required to further elucidate the indications for use, beneficial effects, and recommended treatment schedule of anti-VEGF agents, especially because spontaneous improvement is common.

The neodymium:yttrium–aluminum–garnet laser (Nd:YAG) has been employed in the treatment of dense premacular hemorrhage.<sup>59,60</sup> Nd:YAG photodisruption creates a focal opening in the anterior surface of the preretinal hemorrhage, allowing drainage into the vitreous cavity. In a study of six eyes with preretinal hemorrhage secondary to macroaneurysm formation, all eyes showed improvement of vision within 1 week of Nd:YAG photodisruption.<sup>59</sup> In a retrospective review of 21 eyes with premacular hemorrhage secondary to various causes, visual improvement resulted within 1 month of Nd:YAG photodisruption in 16 eyes.<sup>60</sup> However, seven patients required additional vitrectomy for nonclearing vitreous hemorrhage and complications, including macular hole and retinal detachment. The macular hole occurred in an eye with premacular subhyaloid hemorrhage of only 1 disc diameter. The authors postulated that the small size of the hemorrhage did not provide a sufficient dampening effect for the laser burst, and they subsequently recommended that laser drainage be used only if the hemorrhage is beyond 3 disc diameters in size.<sup>60</sup> This treatment modality can be used for rapid visual recovery but most likely results in a visual outcome no better than that with the natural course of the disease. Furthermore, complications from laser photocoagulation can include hemorrhage, epiretinal membrane formation, retinal toxicity, and arterial occlusion leading to retinal ischemia.<sup>61-63</sup> Long-term studies are needed to better define the risks and benefits of laser photodisruption, especially for hemorrhage associated with RAMs.

Pars plana vitrectomy with the use of tissue plasminogen activator (t-PA) has been advocated for the removal of dense, thick subretinal hemorrhage.<sup>64-69</sup> Patients with submacular hemorrhage secondary to RAM have had generally favorable visual outcomes with this technique.<sup>64,65,67-69</sup> However, McCabe et al., in their retrospective review of 41 cases with macular hemorrhage secondary to RAMs, found that patients managed with observation alone had good visual outcomes that were comparable with those of patients managed surgically.<sup>70</sup> Oie and Emi reported that surgical removal of the macroaneurysm along with the hemorrhage might be of use in cases where it is still felt that surgery is indicated to remove the subretinal hemorrhage.<sup>71</sup> In support of this theory, Koinzer et al. in a case series of 49 patients found that although patients treated with observation, laser, and vitrectomy had similar outcomes at 3 years, patients who underwent surgery initially presented with poorer vision.<sup>46</sup> They suggested that intervention should be determined by the severity of the initial presentation and that surgical management may be appropriate in cases of subretinal hemorrhage threatening the macula.

Investigators have also successfully treated submacular hemorrhage by using pneumatic displacement both with and without adjunct intravitreal t-PA.<sup>72-76</sup> Pneumatic displacement consists of pretreatment with intravitreal t-PA followed by injection of perfluoropropane or sulfur hexafluoride gas and prone positioning for at least 24 hours to compress the macula directly and displace the submacular hemorrhage inferiorly. Because retinal toxic

effects of t-PA have been observed in animal studies, investigators recommend avoiding intravitreal injections of t-PA in concentrations >25 µg/0.1 mL.<sup>72</sup> Likewise, caution was advised in the use of intravitreal t-PA injection in patients with RAMs because of a possible increased risk of vitreous hemorrhage. In one study, Mizutani et al. reported vitreous hemorrhage in all four patients pretreated with t-PA.<sup>75</sup> With concerns of t-PA toxicity, Ohji et al. reported a series of five patients treated with perfluoropropane gas followed by prone positioning, without pretreatment with t-PA.<sup>74</sup> Vision improved, and blood was displaced from the fovea partially or completely in all five patients. Nevertheless, Ohji et al. speculated that solid blood clots present >1 week may not be displaced with gas compression alone.<sup>74</sup>

Several risk factors indicative of a poor visual outcome have been identified in a report by Yang et al., including the presence of foveal exudates and subfoveal hemorrhage.<sup>77</sup> Still, even in the presence of subfoveal hemorrhage, a number of these patients will do well without specific treatment other than observation.<sup>70</sup> Ultimately, the preferred treatment for patients with macular hemorrhage secondary to RAM remains controversial and is often determined on a case by case basis.

# Age-Related Macular Degeneration

Miin Roh, Ivana K. Kim

# 6.29

**Definition:** A common, chronic, progressive degenerative disorder of the macula that affects older individuals and features loss of central vision as a result of abnormalities in the photoreceptor/retinal pigment epithelium/Bruch's membrane/choroidal complex often resulting in geographic atrophy and/or neovascularization.

## Key Features

- Age >50 years.
- Bilateral.
- Drusen.
- Hyperpigmentation of the retinal pigment epithelium (RPE).
- Hypopigmentation of the RPE.
- Geographic atrophy.
- Detachment of the retinal pigment epithelium.
- Macular choroidal neovascularization.

## Associated Features

- Subretinal fluid.
- Intraretinal fluid.
- Subretinal hemorrhage.
- Intraretinal or inner retinal hemorrhage.
- Lipid exudation.
- Subretinal fibrosis (disciform scarring).
- Specific genetic risk alleles, particularly in genes controlling the complement system.

## INTRODUCTION

Age-related macular degeneration (AMD) is the leading cause of irreversible visual impairment among older adults worldwide affecting 30–50 million individuals.<sup>1–5</sup> Loss of visual acuity typically results from progressive degeneration of the photoreceptors, retinal pigment epithelium (RPE), and choriocapillaris, although the earliest manifestation of the disease appears histopathologically as abnormalities within Bruch's membrane. The advanced form of the disease is characterized by choroidal neovascularization (CNV), geographic atrophy (GA; atrophy of the RPE, choriocapillaris, and photoreceptors), or both. The disease nearly always begins as the non-neovascular or dry form of AMD and may progress to GA or the neovascular (wet) form in one or both eyes. When neovascularization occurs, there is accumulation of fluid, hemorrhage, and lipid exudation within the macula that can culminate in fibrosis referred to as a *disciform scar*. It is controversial whether the wet and dry forms of AMD represent two distinct disease entities or end-stage manifestations of the same disease.<sup>6</sup> Once advanced AMD develops in one eye, there is an increased likelihood of having GA or neovascularization in the fellow eye. A simplified severity scale based on fundus appearance was established to assess the risk of converting to advanced AMD.<sup>7</sup> Large drusen, any pigment changes, and the disease state of the fellow eye were particularly predictive for developing advanced AMD. The cause of AMD is multifactorial and influenced by age, ethnic background, and a combination of environmental and genetic factors.<sup>5,8</sup> There is no cure; however, vitamin supplementation, good nutrition, and cessation of smoking can slow the progression of the dry form of AMD,<sup>9,10</sup> and drugs that inhibit vascular endothelial growth factor-A (VEGF-A) have been successful in treating the wet form of AMD.<sup>11–16</sup>

## EPIDEMIOLOGY

Many studies have reported the prevalence of AMD in a variety of populations by using varying definitions.<sup>4</sup> The World Health Organization (WHO) estimated in 2002 that 8.7% of the world's blindness was caused by AMD, with 14 million people being blinded or severely visually impaired because of it. Most of the affected individuals live in developed countries. In general, advanced AMD is rare before age 55 years and more common in persons 75 years of age and older. The prevalence of neovascular AMD and GA appears to vary in different ethnic and racial groups throughout the world. Advanced AMD can be classified broadly into two types: dry and wet AMD. Although dry AMD accounts for the majority of all diagnosed cases, wet AMD is responsible for the majority of the severe vision loss and usually occurs over weeks to months.<sup>17</sup> Although neovascularization has been the most common cause of severe vision loss, GA, the most advanced form of dry AMD, can cause significant loss of vision as well, and this form of blindness, which evolves slowly over years, will become even more common as a result of successful anti-VEGF therapy and as the population ages.<sup>3,4</sup> The prevalence of advanced AMD increases with each decade after age 50 years, with the highest prevalence found among those age >80 years.<sup>3</sup> In 2000, advanced AMD affected more than 1.75 million people in the United States, with that number expected to rise to 3 million by 2020 as the “baby boom” population ages.<sup>3</sup>

## PATHOGENESIS

Insights into the pathogenesis have come through the evaluation of histopathological specimens and genetic association studies in different populations. Early in the disease process, lipids are deposited in Bruch's membrane, possibly from failure of the RPE to process the cellular debris associated with outer segment turnover. These deposits are known as *basal linear deposits* and *basal laminar deposits*. Only later in the disease process are drusen visible. The appearance of drusen is the earliest visible clinical sign of AMD.

Analysis of typical drusen that elevate the RPE reveals that they contain lipid, amyloid, complement factors, and additional cellular components.<sup>18,19</sup> The appearance of drusen is preceded by or concomitant with the thickening of the Bruch's membrane collagenous layers, degeneration of elastin and collagen within Bruch's membrane with calcification of Bruch's membrane, increased levels of advanced glycation end products, and accumulation of lipids as well as exogenous proteins.<sup>20</sup> These changes may serve as a hydrophobic barrier to impede the passage of fluid and nutrients between the choroid and the outer retina, resulting in relative ischemia. Subsequent ingrowth of neovascularization from the choriocapillaris may then occur through fractures in Bruch's membrane.<sup>21</sup>

Family history is an established determinant of risk as best shown from twin studies.<sup>8</sup> In studies of monozygotic twins with AMD and common environmental as well as dietary influences, the fundus appearance and degree of visual loss were strikingly similar (89%–100%). Clinical concordance in dizygotic twins reared in a shared environment was markedly less but still substantial (46%), consistent with typical siblings. The importance of heredity was confirmed when polymorphisms within genes encoding complement factor H, human high-temperature requirement A-1 (HTRA1), complement C2, CFB, and C3 were shown to be predictors of risk for AMD.<sup>22–27</sup> Although it is unknown precisely how genetic variation in the complement cascade predisposes patients to AMD, evidence suggests that dysregulation of the innate complement pathway leads to aberrant inflammatory responses, resulting in the accumulation of debris within Bruch's membrane. Many components of the activated complement cascade, such as C3a and C5a, were previously identified in drusen.<sup>28,29</sup> However, the mechanism whereby the complement pathways initially

**Fig. 6.29.1 Right Eye of a 69-Year-Old Woman With Intermediate Age-Related Macular Degeneration (AMD), Showing Soft Drusen.** (Top left) Color fundus photograph showing the superimposed location of the spectral-domain optical coherence tomography (SD-OCT) dataset indicated by the *white square*. (Top middle) Fundus autofluorescence. (Top right) Retinal pigment epithelium (RPE) segmentation map. (Bottom left) Foveal horizontal B-scan corresponding to the *white line* on the color fundus photograph. (Bottom right) RPE elevation map.

become activated remains to be elucidated. It has recently been demonstrated that the risk of bilateral GA is associated with CFH (complement factor H), whereas HTRA1 attributes more risk to the risk of bilateral CNV. Furthermore, C3 has been shown to confer more risk for GA than CNV.<sup>26</sup> The identification of these genes confirms the genetic component of AMD that and inflammation plays an important role. However, AMD in different ethnic groups may or may not be associated with the same genetic loci or polymorphisms.

The most important environmental risk factors are smoking and obesity.<sup>30</sup> Other risk factors for the development of AMD have been identified despite a limited understanding of the exact pathophysiology. Various researchers implicate atherosclerosis, oxidative damage, phototoxicity, and diet.<sup>4</sup> Evidence of light exposure as a cause of AMD is inconclusive with only a few clinical studies showing a positive association between sun exposure and late AMD.<sup>31,32</sup> However, several case-control studies failed to show an association between sunlight exposure and AMD.<sup>33,34</sup>

## OCULAR MANIFESTATIONS

### Dry AMD

#### *Drusen and Focal Hyperpigmentation of the RPE*

Drusen are one of the earliest signs of AMD. Clinically, typical drusen appear as focal, whitish yellow excrescences deep to the retina. Generally, they cluster in the posterior pole but can appear anywhere in the fundus. Drusen in an extramacular location are of no known visual consequence. Typical drusen deposits are located between the RPE and Bruch's membrane and vary widely in number, size, shape, and distribution. Most drusen are 20–100  $\mu\text{m}$  in diameter and are characterized as hard or soft as well as small ( $<63 \mu\text{m}$ ), intermediate ( $>63 \mu\text{m}$  but  $<125 \mu\text{m}$ ), or large ( $\geq 125 \mu\text{m}$ ).<sup>7,35</sup>

Hard drusen, which appear as round, discrete yellow-white spots, measure  $<63 \mu\text{m}$ . These drusen are commonly identified in many populations; they are not age related and do not carry an increased risk for the development of neovascularization, with approximately 80% of the general population age  $>30$  years manifesting at least one. In contrast, soft drusen

are ill defined, with nondiscrete borders, measuring  $\geq 63 \mu\text{m}$  (Fig. 6.29.1). Different population-based studies and clinical trials have indicated that large, soft, confluent drusen are age related and associated, with a higher risk for development of advanced AMD with the development of neovascularization.<sup>7,32,36</sup> After the age of 70 years, 26% of individuals have large or soft drusen, and 17% have confluent drusen.<sup>37</sup>

Reticular pseudo-drusen, which appear as yellow faint interlacing network, were first identified on blue-light fundus photography,<sup>38</sup> and recent Optos ultra-wide field imaging showed that reticular pseudo-drusen were found in 11% of the AREDS2 cohort.<sup>39</sup> Reticular pseudo-drusen were initially shown to be associated with a high risk of progression to neovascular AMD<sup>40–42</sup> but subsequently found to be equally associated with development of atrophic AMD in a recent epidemiological study.<sup>41,43,44</sup> Although their origin is unclear, the original histopathology localized reticular pseudo-drusen to changes in the choroid with loss of choroidal vessels accompanied by fibrous replacement of choroidal stroma in a reticular pattern.<sup>40</sup> More recent studies have identified them as subretinal deposits above the RPE.<sup>45,46</sup> For the most part, drusen alone do not cause severe visual acuity loss but can be associated with complaints of light adaptation, mild metamorphopsia, loss of reading speed, and impaired contrast sensitivity.

Focal hyperpigmentation of the RPE is another important clinical feature of nonneovascular AMD. The risk of developing soft drusen and GA increases in its presence.<sup>47</sup>

#### *Geographic Atrophy*

GA is clinically seen as one or more well-delineated areas of hypopigmentation or depigmentation because of absence or severe attenuation of the underlying RPE (Fig. 6.29.2). The larger, deep choroidal vessels are more readily visualized through the atrophic patches that also lack photoreceptors and choriocapillaris. These areas are usually small (less than a disc area) and may surround the fovea in a petaloid pattern, and they typically coalesce over time or manifest as one large central lesion up to 7 mm in diameter. If the foveal center is spared, good visual acuity may be preserved, although reading vision may remain poor because of a constricted central visual field. Many eyes that have GA also exhibit drusen. In fact, most cases of GA occur in a pattern corresponding to the regression of

**Fig. 6.29.2 Right Eye of an 84-Year-Old Woman With Advanced Age-Related Macular Degeneration (AMD), Showing Geographic Atrophy.** (Top from left to right) Color fundus photograph, fundus autofluorescence, late phase fluorescein angiography, and optical coherence tomography (OCT) fundus image. (Bottom) Foveal horizontal B-scan corresponding to the *white line* on the color fundus photograph.

prior, significant drusen. Visual acuity loss from dry AMD is generally caused by GA involving the foveal region.<sup>48-51</sup>

## Neovascular AMD

Neovascular or wet AMD is characterized by the presence of neovascularization within the macula. This neovascularization may result from the ingrowth of neovascularization from the choriocapillaris under the macular region, which is typical CNV, or may arise predominantly within the retina and is known as *retinal angiomatous proliferation* (RAP). In the advanced forms of neovascular AMD, it is not unusual to see retinal–choroidal anastomoses, a communication between retinal and choroidal circulations.

Patients often report a sudden worsening of their central vision, often with distortion. The clinical manifestations of neovascular AMD can include the following: subretinal fluid; intraretinal fluid; retinal, subretinal, or sub-RPE hemorrhage; lipid exudates; gray or yellow-green discoloration or plaque-like membrane; RPE detachment; RPE tear (Figs. 6.29.3, 6.29.4 and 6.29.5). In end-stage disease, the neovascularization results in a fibrovascular or atrophic macular scar and subsequent permanent damage to the central vision.

### Detachment of the RPE

A retinal pigment epithelial detachment (PED) may be caused by serous fluid, fibrovascular tissue, hemorrhage, or the coalescence of drusen beneath the RPE. Each has a unique clinical appearance and exhibits specific fluorescence patterns on angiography. Fibrovascular PED represents a type of occult CNV described later. Hemorrhagic PED manifests as a dark elevation of the RPE because of underlying blood, showing blocked fluorescence throughout all phases of angiography. Serous PED appears as a dome-shaped detachment of the RPE, exhibiting bright, diffuse hyperfluorescence with progressive pooling in a fixed space. Drusenoid PEDs, caused by coalescence of drusen, show staining, often with fading fluorescence in the late phase and an absence of leakage.<sup>52</sup>

## DIAGNOSIS AND ANCILLARY TESTING

Clinical examination is usually sufficient to establish a diagnosis of AMD, although subtle macular abnormalities are best detected with the help of

ancillary tests, such as fundus autofluorescence (FAF), optical coherence tomography (OCT), fluorescein angiography (FA), indocyanine green angiography (ICGA), and optical coherence tomography angiography (OCTA).

## Fundus Autofluorescence

FAF represents an imaging modality capable of reflecting the morphological changes associated with the metabolism of lipofuscin. It allows for noninvasive, topographical, in vivo imaging of intrinsic fluorophores in the macula. Depending on the instrument, FAF imaging is obtained using an excitation wavelength ranging from 488 nm to 585 nm and an emission bandwidth of 500–700 nm. Areas of GA exhibit very low to extinguished FAF signals (dark) as a result of loss of RPE and lipofuscin, which leads to a region with a high-contrast transition between the area of atrophy and the perilesional retina (see Fig. 6.29.2). In addition, various patterns of perilesional FAF changes may be predictive of disease progression.<sup>53-56</sup>

## Optical Coherence Tomography

OCT may be a useful ancillary test in any stage of AMD. In patients with dry AMD, the high-definition averaged B-scans are useful to assess the ultra-structure of drusen and to examine adjacent retinal layers that can be compromised by the disease process. The acquisition of raster scans comprising a large number of lower-density B-scans combined with the use of segmentation algorithms results in the ability to generate maps of the internal limiting membrane and the RPE, which provides information on the RPE geometry and therefore a unique perspective of drusen. Currently, segmentation algorithms can be applied to the data set and provide the actual volume and area of drusen (see Fig. 6.29.1).<sup>57,58</sup> The progression of early AMD to severe forms, such as GA, can be monitored by using OCT. The loss of RPE and photoreceptors are easily observed in the B-scans (see Fig. 6.29.2). The area of GA can be measured by using the OCT fundus image (OFI) and the sub-RPE slab OFI.<sup>59,60</sup> The OFI represents a virtual fundus image resulting from the en face summation of the reflected light from each A-scan. This en face OFI identifies GA as a bright area resulting from the increased penetration of light into the choroid where atrophy has occurred in the macula (see Fig. 6.29.2; Figs. 6.29.6 and 6.29.7), whereas

(Bottom right) Retinal thickness map and retinal pigment epithelium (RPE) segmentation map.

the sub-RPE slab OFI is the summation of the reflected light from beneath the RPE.

OCT is more widely used in wet AMD by physicians. High-definition B-scans can be used to identify some of the wet AMD features, such as the presence of intraretinal or subretinal fluid, presence of retinal PEDs, which can be classified in serous (vascularized and nonvascularized), fibrovascular, and hemorrhagic PEDs. The macular fluid can be identified by

examining B-scans and by reviewing retinal thickness maps, which calculate the retinal thickness between the internal limiting membrane and the RPE (see Fig. 6.29.3). Since the advent of drugs that inhibit VEGF, one of the strategies for monitoring eyes with wet AMD has been to use OCT to determine whether the treatment is effective in resolving the macular fluid. The effect of anti-VEGF therapy can then be assessed on the basis of the qualitative appearance of B-scans and the qualitative as well as quantitative

**Fig. 6.29.5** Right Eye of a 78-Year-Old Woman With Advanced Age-Related Macular Degeneration (AMD), Showing Choroidal Neovascularization With a Retinal Pigment Epithelium (RPE) Tear. (Top left) Color fundus photograph. (Top middle) Infrared image. (Top right) Fundus autofluorescence. (Bottom right) RPE segmentation map and retinal thickness map.

changes in retinal thickness maps (Fig. 6.29.8). In addition, the same algorithm used to measure drusen can also be used to reproducibly measure the area and volume of PEDs, thus monitoring the natural history and the treatment effect in wet AMD patients.<sup>61</sup>

OCT also allows the physician to distinguish between causes of visual acuity loss that may not be directly associated with AMD, such as a subtle epiretinal membrane or vitreomacular traction.

## Fluorescein Angiography

FA is usually performed to confirm the presence of CNV and identifies the characteristics of a lesion, including the location and type of abnormal vessels, which may be helpful in serving as a baseline examination for future studies to decide whether treatment has been effective.

On the basis of angiographic patterns of fluorescence, the neovascular lesion may be categorized as type 1 (occult), type 2 (classic), or type 3 (retinomatous angiomatous proliferation). *Type 1* CNV refers to new blood vessels that proliferate underneath the RPE and is also called *occult* CNV. Occult CNV is recognized angiographically by one of two patterns: fibrovascular PED or late leakage from an undetermined source. Fibrovascular PED is characterized by an area of irregular elevation of the RPE (which is neither as bright nor as discrete as in classic CNV), often with stippled hyperfluorescence present in the midphase of the angiogram and leakage or staining by the late phase (see Fig. 6.29.4). Late leakage from an undetermined source usually appears as speckled hyperfluorescence with dye pooled in the subretinal space in the late phase, and the source of the leakage does not correspond to classic CNV or a fibrovascular PED in the early or midphase portion of the angiogram. In *type 2* CNV, new blood vessels are between the neurosensory retina and RPE. Type 2 or classic CNV is characterized by bright, often “lacy,” early hyperfluorescence exhibiting prominent leakage in the late phase (see Fig. 6.29.3). *Type 3* CNV or

RAP forms new blood vessels within or below the sensory retina beginning with capillary proliferation, formation of intraretinal neovascularization, and retinal–retinal anastomoses. This retinal neovascularization then extends beneath the neurosensory retina to become subretinal neovascularization (SRN). With time, SRN may merge with the choroidal circulation beneath the RPE to form retinal–choroidal anastomosis.<sup>62</sup> Angiograms are also evaluated for the presence of hemorrhage, blocked fluorescence that does not correspond to hemorrhage, or serous detachment of the RPE. Neovascularization within the area of the serous detachment may not be identifiable because of intense hyperfluorescence.

## Indocyanine Green Angiography

ICGA has been used to diagnose and guide treatment in patients with AMD. The ICG dye binds to plasma proteins, limiting leakage from choroidal vessels, thus delineating the choroidal circulation better compared with FA. The appearance of CNV based on ICGA may be categorized into three types: focal hot spots, plaques, and a combination of the two (see Fig. 6.29.4). Laser treatment based on ICGA findings has been advocated, but the data remain anecdotal and unproven in any prospective study.<sup>63,64</sup> ICGA is particularly useful in identifying polypoidal choroidal vasculopathy (PCV), a variant of exudative AMD characterized by orange-red nodules and serosanguinous pigment epithelial detachments on ophthalmoscopy. ICGA demonstrates polyps and branching vascular networks in this condition that are often difficult to detect on FA<sup>65–69</sup> (Fig. 6.29.9).

## Optical Coherence Tomography Angiography

Optical coherence tomography angiography (OCTA) is a noninvasive method to visualize blood flow using various algorithms.<sup>70</sup> The motion contrast between the rapidly repeated OCT B scans is used to generate

**Fig. 6.29.6 Right Eye of a 78-Year-Old Man With a Drusenoid Retinal Pigment Epithelial Detachment (DPED) That Collapsed and Formed Geographic Atrophy (GA).** (Top row) Color fundus image, foveal horizontal B-scan, RPE segmentation map, RPE elevation map, and the OCT fundus image at baseline. (Second row) Five months of follow-up. (Third row) 9 months of follow-up. (Bottom row) 16 months of follow-up. Retinal pigment epithelium (RPE) segmentation map (third column) and RPE elevation map (fourth column) show the DPED volume at baseline ( $0.24 \text{ mm}^3$ ) and 5 months ( $0.26 \text{ mm}^3$ ). A collapse of the DPED was observed after nine months of follow-up with development of GA, as seen on the OFI at the 16 month visit (bottom right). The B-scan of the five-month visit shows breakdown of the RPE, with an increased light penetration preceding the collapse of the DPED and the formation of GA.

three-dimensional and depth-resolved images of individual vascular plexuses and segment the inner retina, outer retina, and choriocapillaries without the use of intravenous contrast dye.<sup>71-76</sup> There are several reports<sup>77-79</sup> suggesting that the OCTA is highly sensitive in detecting neovascular complex according to the location of the lesion and can provide depth, area, and flow of CNV.<sup>80</sup> However, signal attenuation from the RPE, media opacity, and retinal hemorrhage still limits precise visualization, and inaccurate segmentation slab design among different instruments is also a major limiting factor in detecting retinal/choroidal vascular abnormalities.<sup>81</sup> The use of a swept source laser centered at a longer wavelength of 1050 nm for OCTA may allow for deeper tissue penetration and better visualization of choroidal vascular pathology.<sup>76</sup> Unlike FA or ICGA, OCTA does not detect dye leakage, which is beneficial for imaging the fenestrated choriocapillaris but is limited in applications where alterations in vascular permeability are markers of disease.

## DIFFERENTIAL DIAGNOSIS

Individuals affected by AMD are typically older adults and have drusen present in the involved or fellow eye. The differential diagnosis of dry AMD includes other conditions that affect the RPE and choriocapillaris (Box 6.29.1). CNV has been described in a variety of ophthalmic conditions (Box 6.29.2), including pathological myopia, inflammatory conditions, choroidal ruptures, ocular histoplasmosis syndrome, and angioid streaks. When CNV is detected, it is important to determine whether AMD is the cause because other causes of CNV may carry different prognoses, which affects counseling and treatment decisions.<sup>66,82,83</sup>

Other causes of subretinal hemorrhage must be ruled out, including retinal arterial macroaneurysm (which usually shows fluorescein leakage from the aneurysm centered along a retinal arteriole). Other causes of subretinal fluid also need to be considered, most commonly central serous chorioretinopathy, particularly the chronic recurrent form that can be seen in older patients. FA, ICGA, FAF, and enhanced-depth OCT imaging are usually helpful in diagnosing central serous chorioretinopathy.<sup>66,84,85</sup>

### BOX 6.29.1 Differential Diagnosis for Dry Age-Related Macular Degeneration

- Hereditary diseases
- Pattern dystrophy
- Stargardt disease
- Best disease
- Angioid streaks
- Central serous chorioretinopathy
- Macular telangiectasia type II
- Multifocal choroiditis
- Acute posterior multifocal placoid pigment epitheliopathy
- Toxic lesions
- Chloroquine
- Phenothiazines
- Canthaxanthin
- Cuticular drusen with or without a vitelliform lesion
- Adult vitelliform dystrophy

## PATHOLOGY

Histopathologically, drusen appear as focal areas of eosinophilic material between the basement membrane of the RPE and Bruch's membrane.<sup>20</sup> They stain positively with periodic acid-Schiff stain. Soft drusen are larger and represent a detachment of the thickened inner aspect of Bruch's membrane along with the RPE. Generally, minimal photoreceptor degeneration overlies drusen.

Bruch's membrane is a five-layered structure in which the basement membrane of the RPE represents the innermost layer.<sup>86,87</sup> The outermost layer is a second basement membrane associated with the endothelium of the choriocapillaris. A zone of elastin is sandwiched on both sides by the inner and outer collagenous layers. An age-related change is the

#### BOX 6.29.2 Partial List of Common Ophthalmic Conditions Associated With Choroidal Neovascularization

- Age-related macular degeneration
- Angioid streaks
- Best disease
- Choroidal osteoma
- Fundus flavimaculatus
- Idiopathic causes
- Multifocal choroiditis
- Ocular histoplasmosis syndrome
- Optic disc drusen
- Optic nerve head pits
- Pathological (progressive) myopia
- Pattern dystrophies
- Photocoagulation
- Sarcoidosis
- Serpiginous or geographic choroiditis
- Toxoplasmic retinochoroiditis
- Traumatic choroidal rupture
- Polypoidal choroidal vasculopathy

**Fig. 6.29.8** Optical coherence tomography (OCT)–guided therapy with treat and extend strategy using anti-vascular endothelial growth factor (VEGF) for the treatment of neovascular age-related macular degeneration (AMD). Patient presented a poor response to ranibizumab with good results after switching to aflibercept. (A) 15th through 42nd ranibizumab injections: OCT images after ranibizumab injection in an eye with neovascular AMD. Horizontal (first column on left) and vertical (second column) OCT scans, retinal pigment epithelium (RPE) segmentation map (third column) and retinal thickness map (fourth column on right) of the left eye are shown before injection of ranibizumab nos. 15, 19, 30, 41, and 42.

appearance of basal laminar deposits, which represent type IV collagen, between the RPE cell surface and the basement membrane. Progressive thickening of this inner part of Bruch's membrane is associated with RPE degeneration. Eosinophilic deposits that coalesce between the RPE basement membrane and the inner collagenous zone of Bruch's membrane are called basal linear deposits. It is difficult to differentiate these two types of deposits with the use of light microscopy. One hypothesis suggests that the material accumulates from damaged RPE cells. Aging also results in increased lipid deposition in Bruch's membrane.<sup>21</sup> Bruch's membrane often shows areas of calcification and fragmentation as well, and these changes are found more commonly in eyes that harbor CNV caused by AMD. The choriocapillaris shows thickened and hyalinized vascular walls, whereas the larger choroidal vessels appear normal. Loss of the RPE in GA is accompanied by loss of the overlying photoreceptors, and the underlying choriocapillaris is also generally hyalinized.

CNV represents new blood vessel ingrowth from the choriocapillaris through a degenerated Bruch's membrane. The earliest histopathological form of CNV consists of fine vessels within Bruch's membrane.<sup>21</sup> Occasionally, a low-grade granulomatous inflammation accompanies CNV. Even when CNV is first noted clinically, the histopathology shows a prominent fibrotic component. The fibrotic component may be associated with hyperplasia or metaplasia of the RPE, overlying retinal atrophy, and cystoid macular edema. Hemosiderin from previous hemorrhage may be seen.

## NATURAL HISTORY AND PROGNOSIS

Early macular degeneration can progress to late manifestations with accompanying vision loss. The risk of progression is highly variable and depends on the severity and extent of the features of early macular degeneration. Drusen and the drusenoid PEDs may progress following different growth patterns. They can increase in volume and area, develop GA (see Fig. 6.29.6) or CNV, remain stable or decrease without any apparent anatomical defect in the macula.<sup>58,88,89</sup> In the course of 5 years, up to 5% of patients with early AMD can progress to late AMD, and the rate increases to nearly 15% in 15 years.<sup>33,90</sup> The Age-Related Eye Disease Study (AREDS) quantified this risk and showed that people with small drusen in both eyes have a very low risk of progression—between 0.4% and 3.0% in 5 years.<sup>7</sup> Hard drusen is a common finding and is not associated with AMD progression. However, soft drusen and RPE changes are associated with a risk of 6.5% and 71%, respectively, for progression to late AMD in a 5-year period.<sup>91</sup> If large drusen and pigmentary abnormalities are present in both eyes, this risk increases to around 47.3%.<sup>7</sup> Several reports support the dynamic nature of drusen with spontaneous resorption of some drusen, as well as the formation of new drusen, and both these activities can occur simultaneously in the same macula.<sup>58,92,93</sup> Regression of soft macular drusen has been described in clinical and histopathological studies.<sup>94-99</sup> Gass first noted that drusen could fade and disappear, leaving only an irregular mottling of the

**Fig. 6.29.8, cont'd (B)** 1st through 4th aflibercept injections: OCT images before aflibercept injection in an eye with neovascular AMD. Horizontal (first column on left) and vertical (second column) OCT scans, RPE segmentation map (third column) and retinal thickness map (fourth column on right) of the left eye are shown before injection of aflibercept no. 1, 2, 3, and 4 with good response and resolution of the persistent subretinal fluid.

RPE but that visual acuity may not be affected. He also observed that most cases of GA occurred after the fading of drusen or the collapse of a serous detachment of the RPE, resulting in degeneration and atrophy of the RPE and photoreceptors (see Fig. 6.29.6).<sup>94</sup> These observations were supported by large population-based studies, in which it was noted that some patients showed drusen regression without any residual defects.<sup>97-99</sup>

GA initially develops as focal areas of depigmentation. Eventually, these coalesce or expand to involve the central macula causing progressive worsening of vision to legal blindness. From the onset of GA, the mean time to legal blindness is 5–9 years (see Fig. 6.29.7).<sup>95,100</sup> Neovascular complications have more of an acute onset with sudden development of central blurring and distortion. If left untreated, the area of neovascularization expands rapidly and a large fibrous scar develops in the macula. A meta-analysis of data from several controlled clinical trials showed that within 3 years of the onset of neovascularization, more than half of untreated eyes will have vision of 20/200 or worse.<sup>101</sup> More than 90% of patients with wet AMD treated with anti-VEGF intravitreal injections will maintain stable vision and one third will have vision improvement.<sup>11,12</sup> Wet AMD is often bilateral, and the risk of a fellow eye being affected is 30% in a 6-year period.<sup>102</sup> The Macular Photocoagulation Study (MPS) reported that the 5-year risk of neovascularization in fellow eyes of individuals with unilateral neovascular AMD was 10% in those without large drusen and 30%–46% in those with large drusen.<sup>103</sup> These risk estimates have been confirmed by the more recent AREDS.<sup>104</sup> The MPS and AREDS showed that in patients with unilateral neovascular AMD, the 5-year risk of developing neovascularization in fellow eyes that manifest both soft drusen and focal hyperpigmentary changes was >50%.<sup>103,104</sup>

## TREATMENT AND PREVENTION

### Dry AMD

Currently, there is no proven therapy that stops the progression of dry AMD. Vitamin supplementation, dietary modification, and cessation of smoking are the current recommendations thought to slow the progression of visual acuity loss in dry AMD.<sup>105</sup> The AREDS (Age-Related Eye Disease Study) study was the first large, prospective trial to show a benefit of antioxidant and zinc supplementation on the progression of AMD and the associated vision loss.<sup>9,106</sup> In these studies, a combination of oral supplementation of vitamin C (500 mg), vitamin E (400 IU), beta-carotene (15 mg), zinc oxide (80 mg), and cupric oxide (2 mg) was beneficial in patients at high risk of developing advanced stages of AMD, lowering the risk by about 25%. The relative risk of vision loss of  $\geq 3$  lines was reduced by 19% in patients taking the supplementation. The high-risk group included patients with advanced AMD in one eye and those with intermediate dry AMD, defined as extensive intermediate-size drusen ( $\geq 63$   $\mu\text{m}$  but  $<125$   $\mu\text{m}$ ), at least one large druse ( $\geq 125$   $\mu\text{m}$ ), or noncentral GA in one or both eyes. Cases of advanced AMD were defined as having any evidence of neovascularization (photocoagulation or other treatment for CNV, hemorrhage under the retina or RPE, or subretinal fibrosis), central GA, or nondrusenoid PED, including serous RPE detachment. Other studies with oral supplementation have demonstrated an increased risk of lung cancer in smokers who take beta-carotene.<sup>107</sup> For this reason, it is recommended that smokers should be offered a form of AREDS vitamin supplementation without beta-carotene. The AREDS 2 study revealed no additional

**Fig. 6.29.9 Right Eye of a 66-Year-Old Female With Polypoidal Choroidal Vasculopathy (PCV).** (A) Color fundus image. (B) Indocyanine green angiography showing polyps. (C–D) Early-phase fluorescein angiography and late-phase fluorescein angiography.

benefit of adding lutein and zeaxanthin (carotenoids), and omega-3 long-chain polyunsaturated fatty acids (docosahexaenoic acid eicosapentaenoic acid) to the original AREDS formula in reducing the risk of AMD progression.<sup>108</sup>

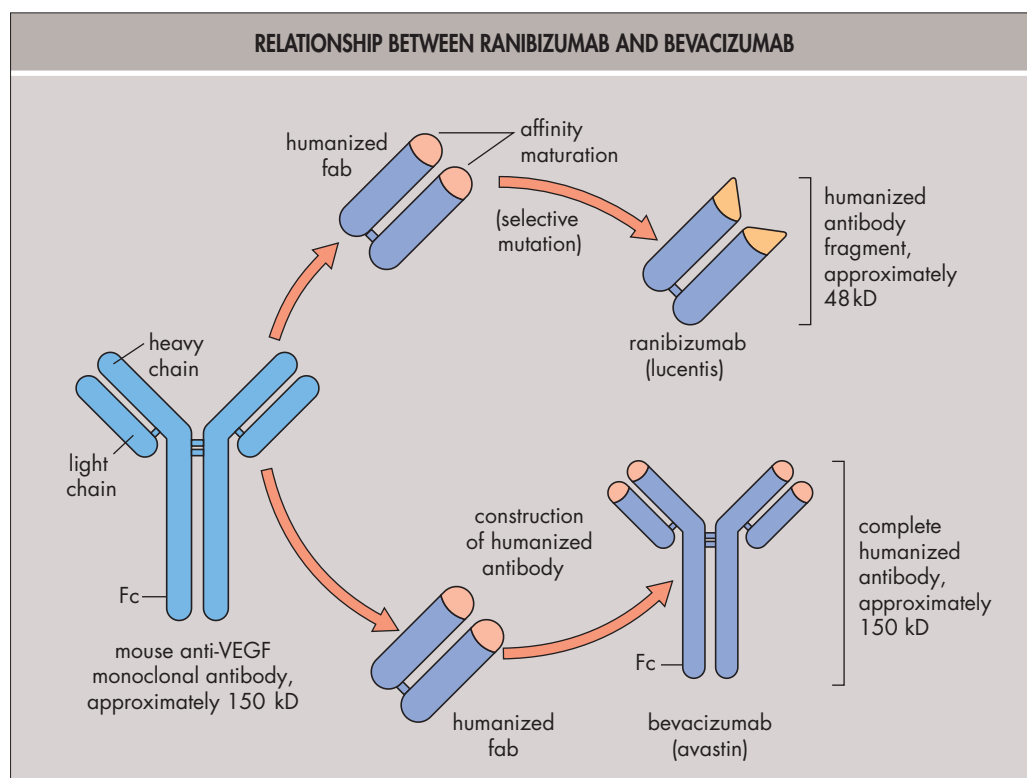

On the basis of the multifactorial pathogenesis of AMD, various strategies have been proposed to treat the nonexudative form of AMD, but these strategies have had limited success to date. Given the genetic association between complement pathway polymorphisms and the risk of AMD, numerous trials of anticomplement drugs have been conducted. Early investigations with a systemic C5 inhibitor (eculizumab) did not show any benefit in reducing GA progression or drusen volume.<sup>109</sup> In phase III studies, the anti-factor D antibody lampalizumab failed to slow the enlargement of GA.<sup>110</sup> A phase IIb/III study for GA with the visual cycle modulator emixustat did not show any difference in lesion growth rate compared with placebo.<sup>111</sup> A small pilot study with high-dose atorvastatin showed promising results with resolution of drusenoid pigment epithelial detachment in patients with high-risk dry AMD.<sup>112</sup> In addition, neuroprotective agents, as well as cell-based and gene therapies,<sup>113–115</sup> are under investigation.

## Neovascular AMD

Several treatments for neovascular AMD have been extensively studied in large, prospective, randomized trials. These include thermal laser photocoagulation,<sup>116–120</sup> photodynamic therapy (PDT) with verteporfin (Visudyne; Novartis Ophthalmics and QLT Inc.), and anti-VEGF drugs, including pegaptanib sodium (Macugen; Eyetech/OSI), bevacizumab (off-label, Avastin; Genentech, South San Francisco), ranibizumab (Lucentis; Genentech, South San Francisco), and aflibercept (Eylea; Regeneron, Tarrytown, NY). Currently, the standard of care for the treatment of neovascular AMD involves the intravitreal injection of bevacizumab or ranibizumab or aflibercept.

## Verteporfin Photodynamic Therapy

PDT uses low-energy light to activate an intravenously injected photosensitizing agent and induce closure of a neovascular complex.<sup>121,122</sup> The goal of PDT is to specifically target neovascular tissue while sparing surrounding and overlying retinal structures.<sup>123</sup>

**Fig. 6.29.10 Relationship Between Ranibizumab and Bevacizumab.** (Redrawn with permission from Steinbrook R. The price of sight: ranibizumab, bevacizumab, and the treatment of macular degeneration. *N Engl J Med* 2006;355:1409–12.)

Two large, prospective trials evaluated verteporfin PDT for the treatment of subfoveal CNV caused by AMD: the Treatment of AMD with Photodynamic Therapy (TAP) study and the Verteporfin in Photodynamic Therapy (VIP) study. At 24 months, the TAP study demonstrated lower rates of moderate vision loss in patients with predominantly classic CNV treated with verteporfin PDT (47%) compared with placebo (62%).<sup>124,125</sup> At 24 months, the VIP study, which included mostly patients with occult CNV but without classic CNV, identified a statistically significant benefit, with 54% in the verteporfin group experiencing moderate vision loss compared with 67% in the placebo group. However, 4% of verteporfin-treated eyes experienced acute severe visual acuity decrease, defined as a loss of  $\geq 20$  letters within 7 days of treatment. Causes of severe visual acuity decrease included hemorrhage, neurosensory detachment, and idiopathic visual acuity loss, which was most likely caused by choroidal infarction.<sup>126</sup>

Attempts to optimize visual acuity outcomes have explored delayed light application in the Verteporfin with Altered Light in Occult CNV (VALIO) study<sup>127</sup> and reduced fluence in the Verteporfin in Minimally Classic CNV (VIM) study.<sup>128</sup> However, no added benefit was observed. Another option pioneered by Spaide<sup>129</sup> was to combine PDT with intravitreal triamcinolone acetonide in the hope of improving visual acuity outcomes with PDT and decreasing the treatment burden.

## Anti-VEGF Therapies

VEGF-A stimulates both angiogenesis and increased vascular permeability and is the major angiogenic factor implicated in the pathogenesis of exudative eye diseases.<sup>130</sup> In humans, four major isoforms of VEGF-A have been identified as a result of alternative RNA splicing (VEGF<sub>121</sub>, VEGF<sub>165</sub>, VEGF<sub>189</sub>, and VEGF<sub>206</sub>), and at least five minor isoforms exist as well (VEGF<sub>145</sub>, VEGF<sub>148</sub>, VEGF<sub>162</sub>, VEGF<sub>165b</sub>, VEGF<sub>183</sub>). The larger VEGF-A isoforms can be cleaved by plasmin and metalloproteinases to produce the diffusible, biologically active, cleavage products VEGF<sub>110</sub> and VEGF<sub>113</sub>, respectively.<sup>131,132</sup> Although VEGF<sub>165</sub> is the most prevalent form of VEGF, all the aforementioned isoforms and proteolytic products are biologically active, with VEGF<sub>121</sub> being the most common isoform in the early stages of experimental CNV in animal models.<sup>133</sup> The consistent correlation between pathological neovascularization in the eye and the expression of VEGF-A provided strong evidence to suggest that inhibition of VEGF-A in the eye could be a viable treatment strategy for the treatment of exudative ocular diseases.<sup>134</sup>

### Pegaptanib Sodium

Pegaptanib sodium (Macugen; Eyetech/Valeant Pharmaceuticals) was the first VEGF-A inhibitor approved by the U.S. Food and Drug Administration (FDA) in 2004 for the treatment of neovascular AMD. Pegaptanib is

an RNA aptamer that binds and inhibits VEGF<sub>165</sub> and larger isoforms of VEGF-A, much like an antibody would bind an antigen.

Two concurrent phase II/III multicenter, randomized, double-blind, sham-controlled, 2-year studies led to FDA approval in 2004. These pivotal clinical trials were known as the VEGF Inhibition Study in Ocular Neovascularization (VISION) trials. In these trials, patients with neovascular AMD were randomized to receive intravitreal injections of pegaptanib sodium (0.3, 1.0, or 3.0 mg) or sham injection at six-week intervals for 48 weeks.<sup>135,136</sup> At 1 year, in 70% of patients treated with 0.3 mg pegaptanib loss of 15 letters was prevented, compared with 55% in the control group ( $P < 0.001$ ). However, only 6% of pegaptanib-treated patients gained at least 15 letters of visual acuity. The 2-year results demonstrated that patients treated with 0.3 mg pegaptanib for 2 years were more likely to maintain visual acuity compared with patients who received usual care for 2 years or who stopped pegaptanib sodium treatment after 1 year.<sup>136</sup>

### Ranibizumab

Ranibizumab is the antigen-binding fragment (Fab) of a monoclonal humanized antibody that binds and inhibits all the aforementioned biologically active forms of VEGF-A (Fig. 6.29.10).<sup>137</sup>

Ranibizumab is administered as an intravitreal injection and received FDA approval in 2006 on the basis of two pivotal phase III trials known as MARINA (Minimally Classic/Occult Trial of the Anti-VEGF Antibody Ranibizumab in the Treatment of Neovascular AMD) and ANCHOR (Anti-VEGF Antibody Ranibizumab for the Treatment of Predominantly Classic Choroidal Neovascularization in AMD). The MARINA trial was a randomized, double-masked, sham-controlled, 2-year study of monthly intravitreal ranibizumab (0.3 or 0.5 mg) in minimally classic or occult CNV secondary to AMD.<sup>12</sup> At 2 years, in 92% and 90% of treated patients (0.3 and 0.5 mg, respectively) a 15-letter loss was prevented compared with 53% in the control group ( $P < 0.001$ ). The mean increase in visual acuity was 5.4 and 6.6 letters for the 0.3 mg and 0.5 mg groups, respectively, while the sham-injected group experienced loss of 14.9 letters for a difference of  $>20$  letters between the sham and treated groups ( $P < 0.001$ ) (Fig. 6.29.11). Visual acuity improvement of at least 15 letters was observed in 26% and 33% of treated patients (0.3 and 0.5 mg, respectively) compared with 4% of sham-injected patients ( $P < 0.001$ ). A treatment benefit was observed in the ranibizumab-treated group compared with the sham group regardless of the patient's gender, age, lesion type, lesion size, or duration of disease.<sup>138</sup> Moreover, the beneficial visual acuity outcomes were associated with improvements in both angiographic and OCT measures.<sup>139</sup>

ANCHOR was a multicenter, randomized, double-masked, 2-year study comparing monthly intravitreal ranibizumab (0.3 or 0.5 mg) with verteporfin PDT in patients with predominantly classic CNV secondary to AMD. At 2 years, in 90% and 89.9% of treated patients (0.3 and 0.5 mg, respectively)

**Fig. 6.29.11 Mean Change from Baseline in Visual Acuity at 12 and 24 Months in the MARINA Study.** (Redrawn with permission from Rosenfeld PJ, Brown DM, Heier JS, et al. Ranibizumab for neovascular age-related macular degeneration. *N Engl J Med* 2006;355:1419–31.)

**Fig. 6.29.12 Mean Change from Baseline in Visual Acuity at 12 and 24 Months in the ANCHOR Study.** (From Brown DM, Michels M, Kaiser PK, et al. Ranibizumab versus verteporfin photodynamic therapy for neovascular age-related macular degeneration: two-year results of the ANCHOR study. *Ophthalmology* 2009 Jan;116(1):57–65.e5.)

a 15-letter loss was prevented compared with 65.7% in the control group ( $P < 0.001$ ). The mean increase in visual acuity was 8.1 and 10.7 letters for the 0.3 mg and 0.5 mg groups, respectively, while the PDT-treated group lost 9.8 letters ( $P < 0.001$ ) (Fig. 6.29.12). Visual acuity improvements of at least 15 letters were observed in 34.3% and 41% of treated patients (0.3 and 0.5 mg, respectively) compared with 6.3% of PDT-treated controls ( $P < 0.001$ ).<sup>14</sup>

### Bevacizumab

Bevacizumab is a full-length humanized monoclonal antibody that binds and inhibits all the biologically active forms of VEGF-A (see Fig. 6.29.10). In 2004, the FDA approved bevacizumab for the treatment of metastatic colorectal cancer. At that time, a study was initiated to explore the off-label use of intravenous bevacizumab for the treatment of neovascular AMD. This study, known as the Systemic Avastin Therapy for Neovascular AMD (SANA) Study, showed that systemic bevacizumab could reduce leakage from CNV and significantly improve vision and decrease OCT central

retinal thickness in patients with neovascular AMD.<sup>140,141</sup> A mild elevation of mean systolic and diastolic blood pressures by 3 weeks (+11 mm Hg,  $P \equiv 0.004$ ; +8 mm Hg,  $P < 0.001$ ) was the only reported adverse event.

In May 2005, the first patient was treated with an intravitreal dose of bevacizumab, and the response appeared identical to the responses previously observed with systemic bevacizumab and intravitreal ranibizumab.<sup>142</sup> Since that initial case was reported, subsequent retrospective and prospective studies have reported significant improvement in mean visual acuity and reduced OCT central retinal thickness in patients with neovascular AMD following monthly or OCT-guided intravitreal bevacizumab at doses ranging from 1.25 to 2.5 mg.<sup>143-165</sup>

### Ranibizumab Versus Bevacizumab

To better assess bevacizumab's safety and efficacy compared with ranibizumab, the National Eye Institute sponsored the Comparison of Age-Related Macular Degeneration Treatments Trial (CATT). The CATT study compared bevacizumab with ranibizumab in neovascular AMD

patients with all major lesion subtypes on either a monthly or “as needed” injection schedule with monthly evaluation. At 1 year, bevacizumab and ranibizumab were equivalent when administered monthly, with an increase of 8.0 and 8.5 letters, respectively. Bevacizumab administered as needed was equivalent to ranibizumab as needed, with an improvement of 5.9 and 6.8 letters, respectively. The proportion of patients who gained at least 15 letters at the end of the first year did not differ significantly among the groups, ranging from 24.9% in the ranibizumab-as-needed group to 34.2% in the ranibizumab-monthly group ( $P = 0.09$ ). In the second year of the CATT trial, patients receiving monthly treatment were randomly reassigned to the as-needed or the monthly treatment group. For both drugs, the visual outcomes at 2 years were slightly better for those maintained on monthly treatment for 2 years compared with those receiving as-needed treatment for both years or only the second year (Fig. 6.29.13). In a period of 1 year, there were no differences between the groups with regard to rates of death, myocardial infarction, and stroke.<sup>13,16</sup>

In the United Kingdom, the Alternative Treatments to Inhibit VEGF in Age-Related Choroidal Neovascularization (IVAN) randomized trial also compared both drugs given on a monthly or as-needed basis. One difference from the CATT trial was that all patients received three consecutive monthly injections to start the trial and three consecutive monthly injections whenever retreatment was required in the as-needed groups. The analyses were inconclusive when comparing the change in visual acuity between both drugs, but the outcomes would have been equivalent if IVAN had used the same noninferiority endpoints as CATT. IVAN did show equivalence when comparing monthly to as-needed treatments at 1 year (Fig. 6.29.14). The serum VEGF level was lower with bevacizumab ( $P < 0.0001$ ) and higher with discontinuous treatment ( $P = 0.004$ ); however, the clinical importance of this finding remains unclear. Regarding safety profiles, arteriothrombotic events and heart failures occurred more often with ranibizumab than with bevacizumab ( $P = 0.03$ ); however, these events occurred in <2% of patients.<sup>15</sup> After 2 years,<sup>166</sup> comparison by drug was inconclusive, using the preset of noninferiority of 3.5 letter limit ( $P = 0.26$ ). Continuous and discontinuous treatments were equivalent for distance VA ( $P = 0.18$ ). Other smaller clinical trials comparing both drugs have been conducted in the United States and Switzerland and showed similar results.<sup>167,168</sup>

## Aflibercept

Aflibercept, a fusion protein containing VEGF receptor ligand-binding domains and the Fc region of immunoglobulin G1 (IgG1), has been studied both as an intravenous and intravitreal drug (Fig. 6.29.15). A phase I/II study using aflibercept intravenously showed efficacy, but the higher dose of 3.0 mg caused dose-limiting toxicities, which included hypertension and proteinuria.<sup>169</sup> Phase III studies (VEGF Trap-Eye: Investigation of

**Fig. 6.29.13 Mean Change from Baseline in Visual Acuity at 12 and 24 Months in the CATT Study.** (From Martin DF, Maguire MG, Fine SL, et al. Ranibizumab and bevacizumab for treatment of neovascular age-related macular degeneration: two-year results. *Ophthalmology* 2012 Jul;119(7):1388–98.)

**Fig. 6.29.14 Mean Best Corrected Visual Acuity Through 24 Months in the IVAN Study.** (From Chakravarthy U, Harding SP, Rogers CA, et al. A randomised controlled trial to assess the clinical effectiveness and cost-effectiveness of alternative treatments to Inhibit VEGF in Age-related choroidal Neovascularisation (IVAN). *Health Technol Assess* 2015 Oct;19(78):1–298.)

Efficacy and Safety in Wet AMD [VIEW] 1 and 2) compared 0.5 or 2.0 mg of intravitreal aflibercept administered monthly for 3 consecutive months, followed by the same doses every 4 weeks or 2 mg every 8 weeks compared with ranibizumab 0.5 mg every 4 weeks. Patients were followed up for 24 months. VIEW 1 was conducted in the United States and Canada and showed that 95%–96% of the patients treated with aflibercept maintained visual acuity compared with 94% in the ranibizumab group. The mean visual acuity improvement from baseline was greater in patients receiving aflibercept 2 mg monthly compared with ranibizumab (10.9 versus 8.1 letters;  $P < 0.01$ ). In VIEW 2, conducted in Europe, Asia Pacific, Japan, and Latin America, 96% of patients in each aflibercept group achieved maintenance of vision compared with 94% in the ranibizumab group. There was no statistically significant difference between the mean change in visual acuity of all groups in VIEW 2 (Fig. 6.29.16).<sup>170</sup> The treatment has shown to be safe and well tolerated in all aflibercept studies.<sup>170-172</sup> In the second year

of VIEW 1 and VIEW 2, patients were followed up monthly with a PRN (Pro ReNata) protocol, but with a maximum interval of 12 weeks between injections. When analyzing VIEW 1 and 2 together, the results obtained in the first year persisted through the second year, with no statistically significant difference between the mean changes in visual acuity and stability of vision in all groups.<sup>170,171</sup>

## Anti-VEGF Treatment Regimens

Intravitreal ranibizumab was the first FDA-approved treatment for neovascular AMD that improved visual acuity outcomes in most patients and prevented the leakage and growth of neovascularization in all the major angiographic forms of CNV. Although these results were impressive, they were achieved by performing monthly intravitreal injections. In an attempt to decrease the burden of monthly injections, alternative dosing strategies were pursued (Fig. 6.29.17).

In the Phase IIIb, Multicenter, Randomized, Double-Masked, Sham Injection-Controlled Study of the Efficacy and Safety of Ranibizumab (PIER) study, patients were randomized to receive either the 0.3 or 0.5 mg dose of ranibizumab or a sham injection. They were treated monthly for 3 consecutive months followed by a treatment every 3 months thereafter. At 2 years, mean visual acuity had decreased an average of 2.2 and 2.3 letters from baseline and only 15% and 8.2% of patients treated gained at least 15 letters (in 0.3 mg and 0.5 mg, respectively).<sup>173</sup> Although these results were better than those in the sham-injected control group, these outcomes were not as good as the visual acuity outcomes of monthly dosing observed in the MARINA and ANCHOR studies.

The EXCITE (Efficacy and Safety of Ranibizumab in patients with Subfoveal CNV secondary to AMD) study was designed to compare monthly regimens with quarterly regimens.<sup>174</sup> The monthly group maintained the initial gains in visual acuity with a final improvement of 8.3 EDTRS letters at 12 months. The quarterly groups had visual acuity improvement at the end of the first 3 months, with a subsequent decline in visual acuity over 12 months of follow-up, showing a gain of 4.9 and 3.8 letters in the 0.3 mg and the 0.5 mg quarterly groups, respectively.

An individualized dosing strategy utilizing OCT was investigated in a study known as PrONTO (Prospective OCT Imaging of Patients with Neovascular AMD Treated with Intracocular Ranibizumab). This phase I/II study enrolled 40 patients and explored whether dosing that was based on the presence of fluid in the macula as detected by OCT could result in fewer injections but achieve visual acuity outcomes similar to the results obtained with monthly dosing.<sup>175</sup> The study design mandated three consecutive monthly injections with intravitreal ranibizumab (0.5 mg). Then, from month 3 through month 24, patients were examined monthly with OCT and additional injections were performed only if certain OCT-based criteria were fulfilled. After 1 year, the mean improvement in visual acuity from baseline was 9.3 letters ( $P < 0.001$ ), and at 2 years, it was 11.1 letters

Fig. 6.29.15 Aflibercept Structure.

Fig. 6.29.16 Mean Change from Baseline in Visual Acuity at 24 Months in the VIEW 1 and VIEW 2 Studies. (From Schmidt-Erfurth U, Kaiser P, Korobelnick JF, et al. Intravitreal aflibercept injection for neovascular age-related macular degeneration. *Ophthalmology* 2014;121:193–201.)

( $P < 0.001$ ). More than one third of eyes (35%) in PrONTO gained at least 15 letters of visual acuity at 1 year and 43% gained at least 15 letters at 2 years. These visual acuity outcomes were comparable with the outcomes in the MARINA and ANCHOR trials. Moreover, these visual acuity outcomes were achieved with an average of 5.6 of a maximum of 13 monthly injections the first year and 9.9 injections out of a maximum of 25 monthly injections over 2 years.<sup>176</sup>

Another OCT-based retreatment strategy known as “treat and extend” has been widely adopted, with the goal of reducing the number of injections and as well as the number of visits while maintaining optimal visual results.<sup>177,178</sup> In this approach, in the absence of signs of exudation based on OCT and clinical examination, injections intervals are gradually extended, typically up to a maximum of 12 weeks. In the LUCAS (Lucentis Compared

to Avastin Study) trial, the treatment interval was extended by 2 weeks at a time, up to a maximum interval of 12 weeks.<sup>179</sup> After 24 months of follow-up, visual results with bevacizumab were equivalent to those with ranibizumab, with 7.4 and 6.6 letters gained with a mean of 18.2 injections for bevacizumab and 16.0 injections for ranibizumab ( $P < 0.001$ ).<sup>180</sup>

To determine if a higher dose of ranibizumab could provide similar or improved visual outcomes with less frequent treatment, the HARBOR trial (Study of Ranibizumab Administered Monthly or on an As-needed Basis in Patients with Subfoveal Neovascular Age-related Macular Degeneration) randomized 1098 patients into four groups: 0.5 mg versus 2.0 mg and monthly versus as-needed dosing following three monthly injections. After 24 months of follow-up, the mean improvement in visual acuity was similar among all treatment groups (+9.1, +8.0, +7.9, and +7.6 letters for the 0.5 mg monthly, 2.0 mg monthly, 0.5 mg as-needed, 2.0 mg as-needed groups, respectively) (see Fig. 6.29.18). The average number of injections in year 2 was 5.6 for the as-needed groups and 4.3 for the 0.5 mg and 2.0 mg groups, respectively. The higher dose of ranibizumab was not proven to provide additional efficacy or durability, but the study provided additional confirmation that OCT-guided treatment with the 0.5 mg dose can achieve the expected visual results with fewer injections.<sup>181</sup>

### Combination Therapies

#### Anti-VEGF Therapy Plus PDT

The combination of anti-VEGF injections and PDT has been explored as a means of reducing injection frequency. The MONT BLANC study compared the efficacy and safety of standard-fluence PDT with as-needed ranibizumab versus as-needed ranibizumab as monotherapy,<sup>182</sup> and the DENALI study compared monthly ranibizumab monotherapy versus as-needed ranibizumab combined with reduced-fluence or standard-fluence PDT.<sup>183</sup> Both studies showed comparable results between monotherapy and combination therapy.<sup>182,183</sup> Moreover the MONT BLANC study did not show that combination therapy significantly reduced the number of ranibizumab injections in 1 year.<sup>182</sup> The verteporfin and bevacizumab (VIA) study<sup>184</sup> was a very small randomized double-masked clinical trial comparing bevacizumab combined with reduced-fluence PDT (25 J/cm<sup>2</sup> and 12 J/cm<sup>2</sup>) versus bevacizumab alone. The investigators found that the combination of bevacizumab with PDT significantly reduced the frequency of bevacizumab retreatment through 6 months.

Although superior functional or anatomical results have not been proven with combination PDT and anti-VEGF therapy in typical neovascular AMD, it does appear that this combination therapy is more efficacious for the polypoidal choroidal vasculopathy. The EVEREST study showed that PDT alone or in combination with ranibizumab was more effective at inducing complete polyp regression at 6 months.<sup>185</sup> One-year results of the EVEREST 2 study further demonstrated that combination therapy

**Fig. 6.29.17** The different treatment strategies using anti-vascular endothelial growth factor (VEGF) therapy for neovascular age-related macular degeneration (AMD).

**Fig. 6.29.18** Mean Change from Baseline in Visual Acuity at 24 Months in the HARBOR Study. (From Ho AC, Busbee BG, Regillo CD, et al. Twenty-four-month efficacy and safety of 0.5 mg or 2.0 mg ranibizumab in patients with subfoveal neovascular age-related macular degeneration. *Ophthalmology* 2014 Nov;121(11):2181–92.)

**Fig. 6.29.19** Mean Change in Visual Acuity in the 7-Year Observational Update of Patients With Age-Related Macular Degeneration (AMD) After the MARINA/ANCHOR and HORIZON Trials. (From Rogagha S, Bhisitkul RB, Boyer DS, et al. Seven-year outcomes in ranibizumab-treated patients in ANCHOR, MARINA, and HORIZON. A multicenter cohort study (SEVEN-UP). *Ophthalmology* 2013;120:2292–99.)

with PDT and ranibizumab achieves better visual outcomes, more complete polyp regression, and fewer injections compared with ranibizumab monotherapy.<sup>186</sup>

### Anti-VEGF Therapy Plus PDGF Inhibitors

Combination pharmacotherapy with other targeted agents is also being explored in the hopes of enhancing antiangiogenic activity. Platelet-derived growth factor (PDGF) binds to PDGF receptors, which are located on fibroblast, pericytes, and vascular smooth muscle.<sup>187</sup> Experimental studies have shown that PDGF inhibitors disturb the pericyte–endothelial interaction, sensitizing VEGF-resistant vessels and facilitating regression of neovessels. Additionally, blocking PDGF also appears to inhibit recruitment of profibrotic cells, such as fibroblasts and macrophages.<sup>188,189</sup> Therefore, dual inhibition of VEGF and PDGF has the potential to be a more potent inhibitor of the neovascularization as well as prevent fibrosis. Two multicenter, randomized, double-masked, controlled phase 3 clinical studies comparing the anti-PDGF agent Fovista (pegpleranib) in combination with ranibizumab to ranibizumab monotherapy showed that there was no visual acuity benefit at month 12 with this combination therapy.<sup>190</sup> The phase II CAPELLA (Study of Intravitreal REGN2176-3 in Patients With Neovascular (“Wet”) Age-Related Macular Degeneration) study evaluating the efficacy of aflibercept co-formulated with rinucumab, an anti-PDGFR-beta antibody, also showed no visual acuity benefit compared with aflibercept monotherapy at 12 weeks.<sup>191</sup> Despite these disappointing results, other targets remain under investigation for potential combined anti-angiogenic therapies.

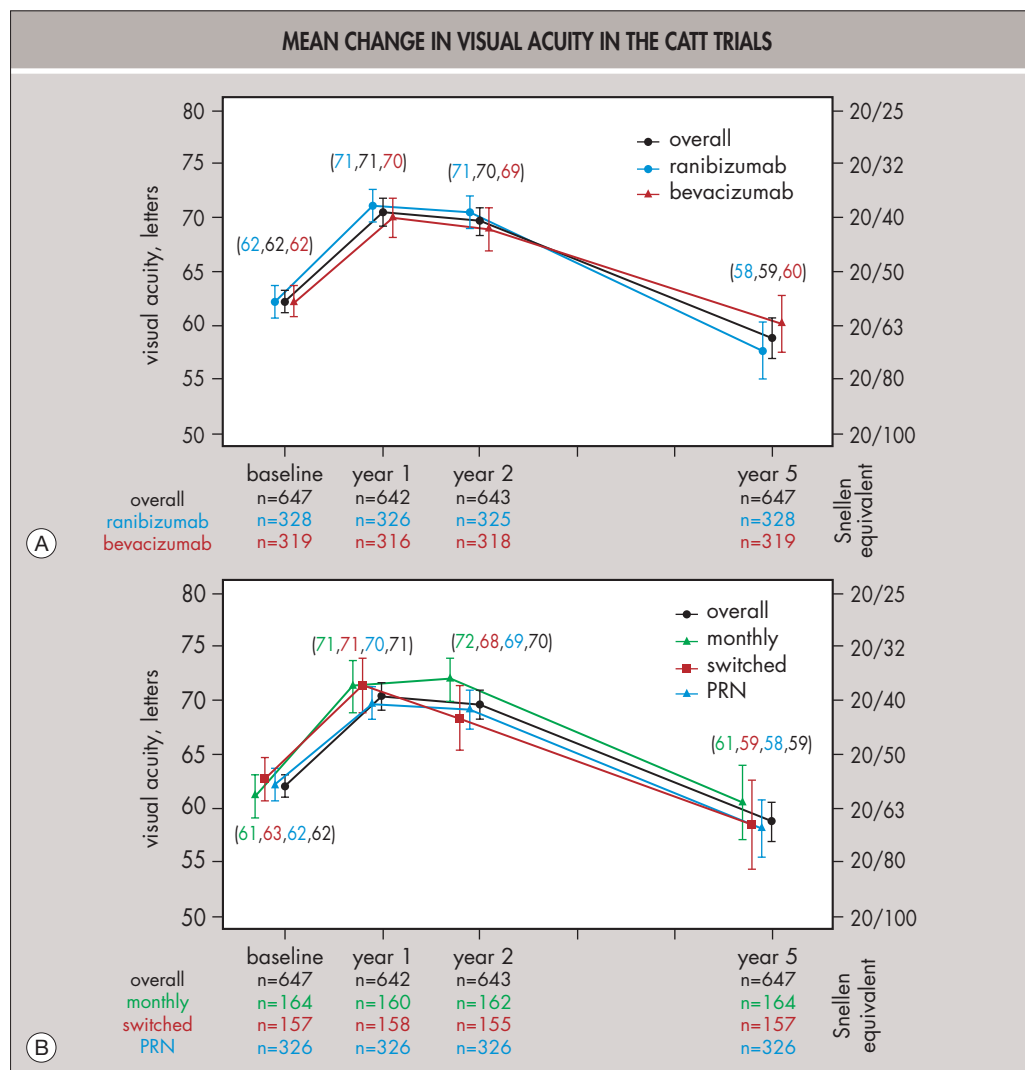

### Long-Term Outcomes With Anti-VEGF Therapy

Compared with the results of anti-VEGF therapy in clinical trials with monthly dosing, long-term visual outcomes in the “real-world” clinical setting appear inferior. The SEVEN-UP study evaluated long-term outcomes in patients enrolled in the ANCHOR, MARINA, and HORIZON trials.<sup>192</sup> Sixty-five patients were followed up for a mean duration of 7.3 years (range, 6.3–8.5 years) after entry into the ANCHOR or MARINA trials. Thirty-seven percent of the eyes had visual acuity better than 20/70, 23% maintained visual acuity better than 20/40, and 37% had visual acuity of

20/200 or worse. Forty-three percent of study eyes had a stable or improved letter score ( $\geq 0$ -letter gain) compared with ANCHOR or MARINA baseline measurements, whereas 34% declined by 15 letters or more, with overall a mean decline of 8.6 letters ( $P < 0.005$ ). After exiting the HORIZON study, study eyes had received a mean of 6.8 anti-VEGF injections during the mean 3.4-year interval; a subgroup of patients who received 11 or more anti-VEGF injections had a significantly better mean gain in letter score compared with time of HORIZON exit ( $P < 0.05$ ) (Fig. 6.29.19). After exit from the CATT trial, 647 patients (71%) were followed up for average of 5.5 years.<sup>193</sup> The mean number of examinations for AMD care after the clinical trial ended was 25.3, and the mean number of treatments was 15.4. Sixty percent of the patients were treated  $\geq 1$  time with a drug other than their assigned drug in CATT. At the 5-year visit, 50% of eyes had visual acuity better than 20/40 and 20% had visual acuity worse than 20/200. Mean change in visual acuity was  $-3$  letters from baseline and  $-11$  letters from the 2-year CATT visit, demonstrating that vision gains were not maintained at 5 years (Fig. 6.29.20).

## CONCLUSIONS

AMD continues to be the leading cause of irreversible visual acuity loss worldwide among older adults. Vitamin supplementation, dietary modifications, and smoking cessation currently remain the only strategies that may slow the progression of dry AMD. For the treatment of wet AMD, ranibizumab, bevacizumab, and aflibercept have revolutionized the prognosis for patients. For the first time, patients can be treated with the expectation that their vision may improve. However, not all patients improve, with 10% losing  $\geq 15$  letters in the course of 2 years, as shown in the phase III ranibizumab trials, and long-term studies<sup>191,192</sup> suggest that the visual acuity gains are not maintained after 5–7 years. The long-term vision loss may be, in some part, related to undertreatment, but it is likely that continued progression of the underlying neurodegenerative process plays a greater role. A multifaceted approach involving prevention, improved drug delivery, and neuroprotective and regenerative strategies will be required to achieve further progress in treatment of AMD.<sup>194</sup>

# Secondary Causes of Choroidal Neovascularization: Conditions Associated With Breaks in Bruch's Membrane

6.30

Richard F. Spaide

**Definition:** Fibrovascular ingrowth associated with defects in Bruch's membrane, which, in turn, can be caused by a number of disease entities.

## Key Features

- Defects in Bruch's membrane resulting from trauma or disease.
- Neovascular proliferation extending into the subretinal space through the defects in Bruch's membrane.
- Hemorrhage and exudation.
- Late scarring.

## Associated Feature

- Each main cause of angioid streaks has associated findings that are helpful in making the correct diagnosis.

The retina, particularly the inner segments, consumes more oxygen per gram compared with any other tissue in the body, yet these same cells have no direct blood supply. Deep to the retina and retinal pigment epithelium is the choroid, a structure with the highest relative blood flow in the body. Separating retina and choroid are two thin, but important layers: the retinal pigment epithelium (RPE) is a single layer of cuboidal cells whose basement membrane forms the innermost aspect of Bruch's membrane, a 2–4 micron thick multilamellar composite. On the outer side of Bruch's membrane is a dense layer of capillaries, the choriocapillaris, whose basement membrane forms the outer aspect of Bruch's membrane. Between these layers are three additional layers, an inner collagenous zone, a middle elastic zone, and an outer collagenous zone. In youth, Bruch's membrane appears to be a tough pliable structure that appears to lose elasticity with aging and disease. Physical defects in Bruch's membrane may develop in a variety of conditions, as will be discussed in this chapter, and all of them have the development of a sight-threatening problem, choroidal neovascularization (CNV), as a potential complication. The clinical course and treatment of CNV varies somewhat with each underlying cause, and understanding of the disease pathogenesis in each can aid in formulating an ideal treatment strategy.

## TRAUMATIC RUPTURES OF BRUCH'S MEMBRANE

Mechanical defects in Bruch's membrane can arise from significant direct trauma to the eye.<sup>1</sup> For example, a racquet ball fits perfectly into the orbit and, when traveling at >100 km/hr, delivers an impressive amount of kinetic energy. The anteroposterior diameter of the eye is suddenly collapsed, and because of increased hydraulic pressure, there is an equatorial expansion of the eye. The induced stresses in the posterior portion of the eye cause curved ruptures of Bruch's membrane that usually course for various distances away from, but concentric with, the optic disc. The close association with the choriocapillaris sets up the significant morbidity that ruptures in Bruch's membrane may portend. The schism in Bruch's

membrane has the potential to rip the choriocapillaris vessels, leading to hemorrhages that dissect up to the subretinal space. The healing response after choroidal rupture includes fibroblast invasion, RPE hyperplasia, and varying degrees of associated neovascularization.<sup>2</sup> The observed neovascularization is a physiological wound healing response that, for most eyes, follows a stereotypical course. The vessels form as part of the fibroproliferative response and eventual scar formation. In the concluding phases of the wound healing response, the vessels ordinarily regress within the scar, leaving bland fibrous tissue. In some eyes, the CNV seems to take on a life of its own and may secondarily cause further tissue damage through bleeding, fluid exudation, and exaggerated scarring. The reasons for the seemingly excessive neovascular response may include greater inflammatory activity, exaggerated wound healing responses, or any number of variations in cytokine responses.

## Treatment

CNV from traumatic choroidal ruptures usually occurs in younger patients, possibly because of the tendency for them to suffer trauma, not because of an inherently increased risk of secondary CNV. The driving forces behind the development of CNV include interplay between vascular endothelial growth factor (VEGF) and potentially many other proinflammatory cytokines. Agents directed against VEGF are a logical part of any treatment strategy, but concurrent anti-inflammatory treatment with a short course of corticosteroids is a reasonable addition for some eyes, particularly if there is clinically evident intraocular inflammation. CNV might not immediately be recognizable as such in eyes with choroidal ruptures after trauma. There are concurrent hemorrhages, and usually early reactive RPE hyperplasia that impede visualization of the underlying choroidal rupture. Fluorescein angiography (FA) shows a focal or more diffuse fluffy border to the choroidal ruptures when early CNV is present. With time, CNV can extend greater distances away from the rupture. Eyes with CNV secondary to choroidal ruptures usually do not require long-term treatment because the neovascularization appears to be part of the wound healing response in general. Aggressive treatment to halt neovascularization and the associated exudation is the first step, to be followed by additional anti-VEGF injections at periodic intervals to prevent possible recurrence of disease. Over the longer term, it is possible to withdraw treatment and achieve a stable outcome (Fig. 6.30.1). There usually is some late flattening and remodeling of the scar.

## ANGIOID STREAKS

Although overt trauma can cause ruptures of Bruch's membrane, fractures can be seen in some conditions without preceding manifest trauma. Because these branching fissures in Bruch's membrane can look like blood vessels, they have been termed *angioid streaks*. These ruptures in Bruch's membrane may be either curvilinear concentric with or radial to the optic disc. There are numerous diseases that cause angioid streaks, but there are a few that account for most of the observed cases. The most common is pseudoxanthoma elasticum (PXE), but other causes are sickle cell anemia and Paget's disease (Fig. 6.30.2).

PXE is a fascinating recessive genetic disorder with considerable phenotypic variability and affects the connective tissue, particularly involving skin, eyes, and the cardiovascular system.<sup>3</sup> Mutations in the *ABCC6*

**Fig. 6.30.1** A 15-year-old male was hit in the eye with a tennis ball and developed loss of visual acuity a few months later. (A) The color fundus photograph taken at presentation shows two curvilinear choroidal ruptures with varying amounts of pigmentation in the central macula. (B) The fluorescein angiogram shows shaggy hyperfluorescence surrounding the streaks. (C) Enhanced depth imaging optical coherence tomography (OCT) shows a nubbin of scar protruding through a defect in the Bruch's membrane/retinal pigment epithelial complex (arrows) and a mound of choroidal neovascularization extending from another defect. Note what appear to be vascular elements in the mound (arrowhead). (D) After intravitreal anti-vascular endothelial growth factor (VEGF) injections, cessation of exudation, and flattening of the macula in the neovascularization were demonstrated.

gene have been identified as causing PXE.<sup>4</sup> *ABCC6* has 31 exons and two closely related, but nonfunctional, pseudo-genes, which makes detection of mutations challenging.<sup>5</sup> Estimates concerning the prevalence of PXE vary, ranging from 1 in 25000 to 1 in 100 000.<sup>6</sup> These estimates are probably too low because some of the >300 different loss-of-function mutations within the *ABCC6* gene do not cause skin abnormalities, the chief manifestation that prompts the clinical diagnosis. The gene encodes a 165-kDa protein that is a member of the C-family of adenosine triphosphate (ATP)-binding cassette proteins.<sup>7</sup> PXE causes skin folds and bumps on the neck and in the arm creases. The yellowish papules and creases present have been likened to chicken skin. Although the typical lesions of PXE involve skin, eyes, and the cardiovascular system, the gene is expressed in the liver and kidneys. As such, it has been hypothesized that PXE is, in fact, a metabolic disease with wide-ranging abnormalities.<sup>8</sup>

The ocular findings include, in addition to angioid streaks, drusen of the optic nerve, peau d'orange, comet-like streaks in the periphery, pseudo-drusen, pockets of subretinal fluid, what has unfortunately been called "pattern dystrophy" to include vitelliform accumulations, and areas of RPE atrophy.<sup>9,10</sup> Angioid streaks develop in regions of confluent calcification of Bruch's membrane, whereas peau d'orange is an appearance caused by spotty incomplete calcification of Bruch's membrane.<sup>11</sup> The typical patient with PXE generally will have regions of subretinal fluid for years and then develop pattern dystrophy-like findings.<sup>10</sup> A year or so after the pattern dystrophy, atrophy, CNV or both will develop. The ingrowth of CNV typically occurs at an angioid streak. Histopathological examination shows calcification of Bruch's membrane with fragmentation of elastic fibers.<sup>12</sup> Although the proportion of patients who develop either CNV or widespread RPE atrophy is not known, these conditions appear to eventually affect the majority of patients with PXE.

The angioid streaks occur in a small proportion of patients with sickle cell disease. These patients also have mineralization of Bruch's membrane and can develop skin changes suggestive of PXE.<sup>13</sup> Curiously, Bruch's membrane is mineralized with calcium, not iron, in cases of sickle disease.<sup>14</sup> CNV can occur secondarily in angioid streaks but seems less common than that seen in patients with PXE. Paget's disease, or osteitis deformans, has a less frequent association with angioid streaks, which also appear to be related to abnormal calcification of Bruch's membrane.<sup>12</sup> Many of the minor causes of angioid streaks appear to be related to abnormalities in mineral physiology and include hypercalcinosis, hyperphosphatemia, and hemochromatosis.<sup>12</sup> The physical defect in Bruch's membrane seems to provide an easy access for blood vessels to grow, but the likelihood of this growth may be modulated by other factors, such as the health of the RPE.

## Treatment

CNV is usually readily apparent in the conditions causing angioid streaks and appears as classic CNV above the plane of the RPE. There is associated exudation and frequently bleeding. Consistent with treatment of CNV secondary to age-related macular degeneration (AMD), the treatment strategies for CNV associated with angioid streaks has evolved over time. Laser photocoagulation has yielded poor results, and photodynamic therapy has not been any better. Each of these treatment modalities was associated with a high proportion of patients experiencing recurrence of neovascularization, with the eventual development of large scars with zones of surrounding atrophy of the RPE. Anti-VEGF agents decrease exudation, bleeding, and scarring in many eyes with CNV and stabilize the visual acuity in the process.<sup>14-16</sup> There are difficulties in treating patients with CNV complicating angioid streaks, particularly those with PXE. In

**Fig. 6.30.2** At presentation, both eyes of this 1-year-old male with pseudo-xanthoma elasticum demonstrated small scattered pockets of subretinal fluid. He eventually developed overt signs of choroidal neovascularization (CNV) in the fellow eye about 1½ years after presentation. (A) The angioid streaks were faintly visible in the midphase of the fluorescein angiogram. (B) (Top) A small region of subretinal fluid is shown in the optical coherence tomography section (*arrow*) at presentation and (bottom) in another region 2 years later. Note the accumulation of shed outer segments, which confer increased autofluorescence signal visible in (C) (*arrows*). (D) Nearly 4 years after presentation, the patient was seen to have a small focus of CNV (*arrow*) emanating from an angioid streak. Treatment of the neovascularization with an anti-vascular endothelial growth factor (VEGF) agent resulted in cessation of leakage from the lesion, as seen on fluorescein angiography (FA), but the patient continued to have subretinal fluid as shown in (B). The chronic presence of fluid makes treatment directed by as-needed (prn) strategies impossible.

younger patients, it is possible to quell the CNV and have what appears to be little sign of disease progression, with disease erupting again later with exudation. During quiescent periods, it is difficult to determine the frequency of dosage to the eyes. In some eyes with PXE, chronic fluid may be present prior to the development of CNV. The subretinal fluid does not go away with anti-VEGF therapy, even if FA shows no signs of CNV activity. Therefore, optical coherence tomography (OCT) findings of subretinal fluid may not serve as a useful means of administering anti-VEGF agents. OCT angiography (OCTA) is a convenient method to image neovascularization and also has shown remarkable abnormalities in choriocapillaris flow.<sup>17</sup> Ordinarily, in the care of CNV in AMD, patients seem respond best with frequent periodic dosing. With angioid streaks, there may be theoretical risk to injection. One report described rapid expansion of angioid streaks after anti-VEGF injection.<sup>18</sup> Minor ocular trauma can be associated with rapid expansion of angioid streaks, sometimes with widespread hemorrhage. During resolution of the hemorrhage, careful FA and indocyanine green angiography (ICGA) may be needed to exclude the possibility of concurrent CNV.

## PATHOLOGICAL MYOPIA

Myopia is the most common ocular abnormality found among populations worldwide. Visually significant sequelae increase in frequency and severity with greater degrees of myopia, and the terms *high myopia* and *pathological*

*myopia* are used to refer to those eyes with > −6.00 diopters (D) of refractive error. The proportion of patients with pathological myopia in the general population ranges from 1%–2% in the United States, but 5%–8% in Japan. In East Asia, the proportions are reaching alarming levels, with 21% of 18-year-old students<sup>19</sup> and 38.4% of university students<sup>20</sup> having a refractive error > −6.00 D in Taiwan.

The ocular expansion in pathological myopia leads to thinning and, in some cases, tractional changes in every layer of the eye, including retinal detachment, myopic macular schisis, macular hole, and zonal areas of chorioretinal atrophy. Breaks in Bruch's membrane are frequent, but look different from angioid streaks. In pathological myopia, the breaks in Bruch's membrane are shorter, less wide, usually not red (possibly because of the underlying choroidal thinning and atrophy<sup>21</sup>), and are usually arranged in a crisscrossing network of shorter lines in the posterior staphyloma. As a consequence, these ruptures in Bruch's membrane are referred to as "lacquer cracks." The number and extent of lacquer cracks increases over time<sup>22</sup> but are not associated with the high proportion of bleeding that is seen in traumatic breaks in Bruch's membrane. Lacquer cracks are important risk factors for the development of CNV in pathological myopia.<sup>23</sup>

## Treatment

Intravitreal injection of anti-VEGF agents revolutionized the treatment of myopic CNV. The initially reported studies were patient series using

bevacizumab, which showed visual acuity gains.<sup>24,25</sup> Later, in randomized studies, ranibizumab and aflibercept were used. In the 12-month RADIANCE study,<sup>26</sup> patients with myopic CNV were randomized to one of two groups receiving ranibizumab, and a third group received verteporfin photodynamic therapy. The patients in the ranibizumab arms were treated with one injection and thereafter on the basis of disease activity. The two groups receiving ranibizumab showed 12.1 and 12.5 letter improvement, whereas the photodynamic therapy group had a mean improvement of 1.4 letters. In the 48-week MYRROR study,<sup>27</sup> 122 patients were randomized to intravitreal aflibercept (n = 91) or sham (n = 31). Patients received one injection at baseline and subsequent injections for CNV persistence or recurrence as determined at monthly examinations. By week 48, the aflibercept group gained 13.5 letters, and the sham group gained 3.9 letters.

In as-needed (prn) strategies, the number of required treatments seems much lower than that for patients with CNV secondary to AMD; many patients may require only one injection in the first year, according to findings of the RADIANCE and MYRROR studies. The catch is that prn strategies often rely on detecting changes caused by CNV activity, which can either be subtle or difficult to detect in eyes with high myopia. The vision results of a single dose followed by prn treatment are known, but it is not known if this is the best strategy for long-term acuity improvement. Patients with high myopia often have subjective complaints of vision problems and measurable declines in visual acuity, but no observable change in OCT imaging results. Injection of anti-VEGF agents in these eyes often causes a reduction of symptoms and improvement in visual acuity. Therefore, a wider range of criteria should be used in prn strategies than what is typically done for AMD. Although the treatment may not directly cause atrophy, the development of atrophy is common, as seen with longer-term follow-up of patients treated with anti-VEGF agents for CNV. The atrophy is likely to be related to both the disease process and the underlying widespread choroidal atrophy in these eyes.

## INFLAMMATORY DISORDERS

Inflammation and angiogenesis frequently coexist. In the process of angiogenesis, there is remodeling of surrounding tissue to allow access for the growing vessels. The tissue remodeling is mediated by a number of factors, including matrix metalloproteinases.<sup>28</sup> As such, a physical disruption of barriers, Bruch's membrane being one of them, is not required for ingrowth of neovascularization.<sup>29</sup> The growing tissue is capable of clearing its own path through these barriers. A salient example of this is how CNV frequently can occur in active phases of multifocal choroiditis panuveitis.<sup>30</sup> (Another disorder, termed *punctate inner choroidopathy*, appears to be a subset of multifocal choroiditis and panuveitis and will be included in the more general term.<sup>31</sup>) These patients have multiple foci of inflammation that is centered, not in the choroid but in the sub-RPE space and in the outer retina.<sup>31</sup> Some of these lesions may have associated CNV that presumably breached the Bruch's membrane barrier without the need for any mechanically induced crack or dehiscence. The driving influence for the CNV was inflammation.

In other instances, inflammatory damage may cause collateral damage to barriers, such as Bruch's membrane. After the acute inflammatory stage, a pock mark of scar and tissue loss that creates the "punch out" lesion is seen in presumed ocular histoplasmosis<sup>32</sup> or in multifocal choroiditis and panuveitis. Bruch's membrane within these lesions may be damaged such

that there could potentially be free communication from the choroid to the sub-RPE or subretinal space. In this regard postinflammatory damage has some similarities to the anatomical configuration related to typical cracks in Bruch's membrane seen in angioid streaks. The major differences are the initial state of Bruch's membrane and what caused the defect to occur. In inflammatory conditions, Bruch's membrane has been found to be healthy initially and then suffers damage from inflammation, leading to breakdown of its architectural structure. In angioid streaks, there is a defect in Bruch's membrane that renders it brittle and susceptible to mechanical dehiscence from the ordinary wear and tear of life.<sup>12</sup> In choroidal ruptures, there is application of force through trauma that is beyond the mechanical strength of Bruch's membrane. Although in presumed ocular histoplasmosis, inflammatory cells are not clinically evident, in animal models, nests of lymphocytes have been shown to become activated with antigen challenge well away from the eye.<sup>33</sup> In CNV developing in clinically quiescent periods of posterior uveitis, such as that associated with multifocal choroiditis and panuveitis or serpiginous choroidopathy,<sup>34</sup> neovascularization is typically responsive to corticosteroids in a way that suggests that inflammation is at least playing a part in the neovascular drive seen in these eyes. In addition, long-term immunosuppression reduces the risk of severe visual loss,<sup>35</sup> highlighting the detrimental effect inflammation may have in the development of neovascularization. This suggests that the development of CNV in eyes with inflammatory damage may be a function of both ease of access of blood vessels into the sub-RPE and subretinal spaces through the defect in Bruch's membrane as well as the enhanced tendency toward this because of concurrent inflammation.

# Central Serous Chorioretinopathy

Ananda Kalevar, Anita Agarwal

6.31

**Definition:** An idiopathic chorioretinal disorder characterized by serous detachment of the neurosensory retina in the macular region.

### Key Features

- One or more focal areas of subretinal fluid in the macula.
- One or more areas of retinal pigment epithelium (RPE) detachment.
- One or more areas of intraretinal fluid.
- One or more focal leaks at the level of the RPE on fluorescein angiography (FA).
- One or more patches of staining at the level of the RPE on FA.
- Hyperpermeability of the choroid on indocyanine green angiography (ICGA).
- Thickening of the choroid on optical coherence tomography (OCT).
- Mottling of the RPE.
- Yellowish white subretinal deposits.
- Unilateral or bilateral involvement.
- Recurrences and chronicity.
- Dependent, bullous retinal detachment.
- Secondary choroidal neovascular membrane.

### INTRODUCTION

Central serous chorioretinopathy (CSCR) is a retinal disorder characterized by serous retinal detachment in the macula (Fig. 6.31.1) affecting mostly young men ages 20–45 years. The male/female ratio varies from 3:1–10:1 in various studies, depending on region and ethnicity.<sup>1</sup> Since its initial description as *relapsing central syphilitic retinitis* by von Graefe in 1866, it has been referred to by many names, including *central serous retinopathy*, *central serous pigment epitheliopathy*, *angiospastic retinopathy*, and *central serous retinitis*. Common symptoms of CSCR include metamorphopsia, blurred vision, and micropsia. If the detachment remains outside the central macula, patients are asymptomatic. Often the serous detachment resolves spontaneously. Visual disturbances typically take several months to resolve. There can be relative preservation of retinal function

**Fig. 6.31.1 Fundus Photograph of Central Serous Chorioretinopathy.** Note the neurosensory retinal detachment the size of two disc diameters in the macular region. (Courtesy West Coast Retina.)

and vision despite prolonged separation of the photoreceptors from the retinal pigment epithelium (RPE). If the macular detachment fails to resolve spontaneously, treatment includes laser photocoagulation<sup>2,4</sup> and photodynamic therapy (PDT),<sup>5-13</sup> which accelerate resorption of subretinal fluid and improves vision.

### EPIDEMIOLOGY AND PATHOGENESIS

Idiopathic CSCR typically affects young to middle-aged adults. In patients age >50 years, CSCR can be difficult to distinguish from age-related macular degeneration (AMD) or the more recently described pachychoroid maculopathy. Men are much more commonly affected compared with women. The age and sex-adjusted incidence of CSCR in a recent population-based study was found to be 5–6 per 100 000 people.<sup>14</sup> The incidence in males was found to be approximately six times higher than in women.<sup>14</sup> Corticosteroids, either endogenous or exogenous, have been associated with CSCR. Other medications and systemic disorders that have been reported as risk factors are listed in Box 6.31.1. CSCR has been produced experimentally in animals by repeated intravenous epinephrine (adrenaline) injections.<sup>15</sup>

The understanding of the pathogenesis of the disorder is incomplete. Recent multimodal imaging technology has revealed some new information. Few pathological studies are available, and the observations from angiographic, clinical, and experimental models are subject to interpretation. It is known, however, that the subretinal fluid originates from the choroid. Dye leakage through an abnormal focal defect at the level of the RPE and its accumulation in the subretinal space are seen clearly on fluorescein angiography (FA)<sup>2</sup> (Fig. 6.31.2).

The cause of the focal RPE leak is unclear. Historically, it was believed that a simple breakdown of the blood–retinal barrier at the RPE level was responsible for the leak. However, this theory does not explain the beneficial effect of the permanent RPE barrier breakdown produced as a result of laser photocoagulation. It was later suggested that pathologically hypersecreting RPE cells cause fluid accumulation, but this theory fails to explain the widespread choroidal hyperpermeability seen with indocyanine green angiography (ICGA)<sup>15</sup> (Fig. 6.31.3). Enhanced depth imaging optical coherence tomography (EDI-OCT) has demonstrated increased choroidal thickness and congestion, and this corroborates the theory that choroidal hyperpermeability plays an important role.<sup>16</sup> *Pachychoroid* is a term that has been introduced in the literature to describe a collection of choroidal findings, most notably a thickened choroid seen on EDI-OCT and large choroidal (pachy) vessels.<sup>17</sup> Pachychoroid pigment epitheliopathy is believed to be a “forme fruste” of CSCR, where a constellation of findings, such as a thickened choroid, reduced fundus tessellation, and RPE abnormalities, is

#### BOX 6.31.1 Reported Risk Factors and Associations With Central Serous Chorioretinopathy

Systemic Conditions	Medications
Type A personality	Corticosteroids
Emotional stress	Psychopharmacological medications
Systemic hypertension	3, 4-methylenedioxymethamphetamine
Gastroesophageal reflux disease	Antacids and antireflux medications
Pregnancy	Over-the-counter sympathomimetics
Organ transplantation	Antibiotics
Systemic lupus erythematosus	Antihistamines
Tobacco use	Sildenafil citrate
Alcohol use	
Membranoproliferative glomerulonephritis type II	
<i>Helicobacter pylori</i> infection	
Autoimmune disorders

seen clinically, and on OCT there is partial or total loss of the choriocapillaris overlying the “pachy” vessels.<sup>17</sup>

Increasing evidence implicates an abnormal choroidal circulation as the cause of CSCR. Using ICGA, Prunte and Flammer<sup>15</sup> showed delayed choroidal capillary lobular filling in areas of hyperpermeability. Choroidal fluid passes through an opening in the RPE and produces a serous retinal detachment.<sup>18</sup> Studies have revealed that corticosteroids can stimulate the production of nitric oxide, prostaglandins, and free radicals within the choroidal circulation.<sup>19</sup>

## OCULAR MANIFESTATIONS

Although unilateral metamorphopsia is the classic symptom of CSCR, patients may also present with unilateral blurred vision, micropsia, impaired dark adaptation, color desaturation, delayed retinal recovery time to bright light, and relative scotoma. Visual acuity ranges from 20/15 to 20/200 with an average of 20/30. A temporary hyperopic shift in refraction may occur. Symptoms typically resolve after several months but may linger even after the fluid resolves as a result of distortion of the receptor endplates; rarely do they persist indefinitely. Permanent sequelae include metamorphopsia, decreased brightness perception, and altered color vision.<sup>2</sup>

CSCR can sometimes present as a bullous, inferior peripheral serous retinal detachment. This is especially true in some patients who receive high doses of corticosteroids either inadvertently for an associated systemic condition or sometimes as a result of misdiagnosis as Vogt-Koyanagi syndrome or sympathetic ophthalmia. The presence of subretinal fluid tracking or “guttering” in recurrent or chronic CSCR, first described by Yannuzzi et al.,<sup>20</sup> from the macular region to the periphery is seen best with wide-field FA and wide-field fundus autofluorescence (FAF) imaging (Fig. 6.31.4).<sup>21</sup>

A chronic form of CSCR occurs in about 5% of cases, most commonly in older individuals and in patients receiving long-term low-dose corticosteroids.<sup>19,22</sup> Chronic CSCR is characterized by a diffuse retinal pigment epitheliopathy that progresses in conjunction with persistent or intermittent presence of subretinal fluid. The retinal detachments tend to be shallow and more diffuse than in the classic form. Cystic intraretinal changes can occur late in the presence of chronic subretinal fluid. The visual prognosis is more guarded because of progressive loss of outer retinal elements, and early treatment is strongly recommended.

## DIAGNOSIS

The diagnosis of CSCR is through clinical examination and subsequent confirmation with FA, FAF, and OCT imaging. ICGA also helps establish the diagnosis but is reserved for those eyes with no definite leak observed on FA. The information derived from multimodal testing is critical to detect the extent of the chorioretinal abnormalities, to monitor the disease, and to exclude other diseases.

Biomicroscopically, a transparent or translucent blister in the posterior pole between the neural retina and the RPE is seen. Shallow detachments may be difficult to discern clinically, and OCT is helpful in diagnosing these cases.<sup>2</sup> The subretinal serous fluid within the blister is often transparent. This fluid may have a protein content and fibrin and be turbid or yellowish, especially in patients who are pregnant or have increased pigmentation, have concurrent diabetes, or are on steroids.<sup>2,22</sup> OCT can demonstrated hyperreflective dots consistent with punctate precipitates and white material within the serous retinal detachment just under the retina.<sup>23</sup> Hypotheses for these yellow precipitates range from shed photoreceptor outer segments to accumulations of fibrin or lipid, or macrophages attempting to clear them.

**Fig. 6.31.5** (A) Fundus photograph of an eye with resolved central serous chorioretinopathy. Note diffuse chronic pigmentary changes in the superior macula. (B) Spectral-domain optical coherence tomography (SD-OCT) of the eye with resolved central serous chorioretinopathy. Note the thickened choroid and the outer retinal loss. (Courtesy West Coast Retina.)

Oval, yellow-gray RPE elevations beneath the detachment may also be seen. These are generally less than one fourth of a disc diameter in size and are surrounded by a faint grayish halo. FA and OCT identify them as retinal pigment epithelial detachments (RPEDs) and frequently demonstrate the focal RPE leaks responsible for the serous retinal detachment within their borders. Because subretinal exudative fluid may track inferiorly in response to gravity, a leaking RPED may lie beyond the superior margin of its retinal detachment. Wide-field autofluorescence imaging is invaluable in detecting the hypoautofluorescent tracts left by guttering fluid and the hyperautofluorescence from the protein-rich subretinal fluid.<sup>24,25</sup>

The presence of cystic retinal degeneration, fine RPE mottling, or RPE clumping suggests chronicity of the present episode or a history of a previous CSCR episode (Fig. 6.31.5). Additional ophthalmoscopic findings, such as lipid or hemorrhage, are rare and should call into question the diagnosis of idiopathic CSCR or suggest the presence of choroidal neovascularization (CNV) in the setting of CSCR.<sup>2</sup> The fellow eye may show evidence of either concurrent or previously resolved CSCR, manifesting as focal areas of RPE rarefaction or small asymptomatic RPEDs.

FA is used to exclude the presence of other pathologies that produce serous retinal detachments and to confirm the diagnosis. Classically, dye from the choroid leaks through a focal RPE defect and pools in the subretinal space. In >75% of patients, this pooling occurs within 1 disc diameter of the fovea.<sup>26</sup> Less pooling may be observed in older lesions in which the RPE exudate has become inspissated.<sup>2</sup> FA features of acute central serous chorioretinopathy include the “expanding dot” or “ink blot” sign of a leaking small PED, or a “smoke stack” sign, where the PED has a focal defect in the overlying RPE and the dye streams out of this defect into the surrounding subretinal fluid. In eyes with chronic CSCR, fluorescein shows mottled hyperfluorescence with gradual staining. The inactive lesions show transmission hyperfluorescence at sites of RPE changes. When FA is atypical, ICGA can help exclude the presence of other pathology. ICGA of CSCR classically reveals bilateral multifocal hyperfluorescent areas. These appear during the midphase of the angiographic procedure and are later silhouetted against larger choroidal vessels as the dye diffuses through the choroid.<sup>27</sup>

OCT is a noninvasive technique that can demonstrate the presence of subretinal fluid (Fig. 6.31.6), RPEDs, and thickening of the choroid. In

**Fig. 6.31.6** Spectral-Domain Optical Coherence Tomography (SD-OCT) Image of an Eye With Acute Central Serous Chorioretinopathy. Note the thickened choroid, a couple of pigment epithelial detachments and significant subretinal fluid. (Courtesy West Coast Retina.)

cases of CSCR, OCT is also used to quantify and monitor the amount and extent of subretinal fluid, thickening of the neurosensory retina, and diminution of the choroidal thickening after treatment.<sup>28</sup>

CSCR can be complicated by type 1 sub-RPE CNV, and this can be difficult to distinguish because both entities share many clinical and multimodal imaging features. The treatment algorithms are quite different because CSCR can be treated conservatively and CNV requires anti-vascular endothelial growth factor (VEGF) therapy. Optical coherence tomography angiography (OCTA) is a technique that has the potential to shed light on this dilemma and reveal CNV in CSCR, thereby permitting prompt treatment.<sup>29</sup> OCTA demonstrated the presence of CNV at the level of the choriocapillaris in a 68-year-old man of Japanese descent with myopia (Fig. 6.31.7A and B). This patient responded to monthly bevacizumab injections, with resolution of subretinal fluid after one treatment.

FAF can help delineate the edge of the area of RPE dysfunction. There is hyperautofluorescence secondary to either collection of the shed photoreceptors or abnormal accumulation of lipofuscin and A2E within the RPE (see Fig. 6.31.4).<sup>30</sup>

## DIFFERENTIAL DIAGNOSIS

Numerous diseases of the choroid, RPE, and retina can produce serous detachments of the neurosensory retina in the macular region. These include CNV, optic disc pits, polypoidal choroidal vasculopathy, choroidal hemangioma, choroidal melanoma, choroidal metastasis, peripheral retinal breaks, posterior uveitis (e.g., Vogt-Koyanagi-Harada’s disease and sympathetic ophthalmia), optic neuritis, papilledema, vitreous traction, macular holes, and systemic hypertension.

CNV, polypoidal choroidal vasculopathy, or an optic disc pit are important diseases that mimic CSCR by producing similar clinical findings, including serous macular retinal detachment, RPE changes, RPED, and subretinal exudate. Consequently, their presence should be excluded through careful clinical examination and ancillary testing. If the FA result is inconclusive, ICGA and OCT can be performed. ICGA of subretinal CNV usually reveals only one area of hyperfluorescence that progressively enlarges during the later frames of the study. ICGA of polypoidal choroidal vasculopathy demonstrates small-caliber, polypoidal choroidal vascular lesions and no areas of choroidal hyperpermeability.<sup>31</sup> An area of CSCR leakage should remain constant or regress with time, whereas a choroidal neovascular membrane will likely enlarge. OCTA can be particularly helpful where there is suspicion of CNV.<sup>28</sup> OCT and FA of the optic nerve is helpful in evaluating the presence of an optic disc pit. EDI-OCT shows choroidal thickening in CSCR and not in the three other mimicking diseases.<sup>16</sup>

## SYSTEMIC ASSOCIATIONS

Usually, CSCR is an isolated idiopathic ocular disorder. However, numerous risk factors and associations have been reported with CSCR (see Box 6.31.1). The most common association seems to be type A personality traits or a recent episode of stress.<sup>2,32</sup> CSCR has been associated with hypercortisolism and systemic corticosteroid use (oral, intravenous, inhaled, epidural, intra-articular, intramuscular, intranasal, topical dermatological applications).<sup>33-35</sup> The observation of increased CSCR symptoms during periods of increased corticosteroid use, and their subsequent resolution

**Fig. 6.31.7** (A–B) Optical coherence tomography angiogram shows presence of choroid neovascularization (CNV) at the level of the choriocapillaris in a 68-year-old man of Japanese descent with myopia and central serous retinopathy. He responded well to monthly bevacizumab injections, with resolution of subretinal fluid after one treatment. (Courtesy West Coast Retina.)

when dosages are decreased, led to this discovery. Bouzas et al.<sup>33</sup> reported CSCR prevalence of 5% among patients with endogenous Cushing's syndrome. A recent genetic study evaluated glucocorticoid receptor (*NR3C1*) and mineralocorticoid receptor (*NR3C2*) genes and found an association with the variants of *NR3C2* genes with chronic CSCR.<sup>36</sup> It is still too early to interpret the relevance of these findings.

Multiple systemic conditions or diseases have been associated with CSCR. These include systemic hypertension,<sup>19,37,38</sup> pregnancy,<sup>39,40</sup> dialysis,<sup>41</sup> organ transplantation,<sup>42</sup> systemic lupus erythematosus,<sup>43</sup> gastroesophageal reflux disease,<sup>44</sup> membranoproliferative glomerulonephritis type II,<sup>45</sup> *Helicobacter pylori* infection,<sup>46</sup> and autoimmune disorders.<sup>37</sup>

Several classes of medications or drugs other than corticosteroids have also been reported to be significantly associated with CSCR. These medications include the following: psychopharmacological medications,<sup>19</sup> antacids and antireflux agents,<sup>44</sup> over-the-counter sympathomimetics,<sup>47</sup> antibiotics (oral),<sup>37</sup> antihistamines,<sup>37</sup> sildenafil citrate,<sup>48</sup> and 3,4-methylenedioxymethamphetamine.<sup>47</sup> In addition, tobacco and alcohol use have been reported to be risk factors for CSCR.<sup>37</sup>

## PATHOLOGY

There are limited pathological studies due to the benign course of CSCR and the low incidence among older adults. In those few performed, the RPE, choroid, and retinal vessels appear normal. The only histopathological changes observed include serous RPEs, subretinal fibrin, serous

detachments of the collagenous portion of Bruch's membrane, and cystic degeneration in the outer layers of the detached retina.<sup>2</sup>

## TREATMENT

Because the vast majority of cases of acute CSCR resolve spontaneously over time, the initial treatment of choice is observation. If the patient is using corticosteroids, these should be discontinued, if medically possible. Despite isolated reports, no medical therapy has been of proven value. Recently, mineralocorticoid antagonists and rifampin have been proposed as safer alternatives to local treatments.<sup>49–58</sup> At this point, the evidence is inconclusive to support their use, and future studies are needed to elucidate their effectiveness.<sup>59</sup> Local treatment options that have been proven to be effective for CSCR include either laser photocoagulation or PDT. Anti-VEGF agents have been attempted to treat CSCR; however, this remains inconclusive unless CNV is present.<sup>60</sup>

Because most CSCR cases resolve spontaneously, laser treatment is reserved for patients with extrafoveal leaks who fail to improve after 3–6 months, demonstrate permanent changes from CSCR in the fellow eye, demonstrate multiple recurrences, or require improved vision for work. Laser treatment should be avoided if the leak occurs within 200  $\mu$ m of the center of the foveal avascular zone, although PDT with reduced fluence can be considered in these situations in chronic recalcitrant cases after careful discussion with the patient.<sup>4</sup>

Laser photocoagulation is applied to the leakage spot(s) as seen on angiography. Although this has been proven to reduce the duration of the serous detachment, it has no effect on the final visual prognosis, hence is reserved for selected patients.<sup>3,4</sup> It is the only therapy with benefit as proven by large clinical trials. The technique of laser photocoagulation involves using a green-wavelength laser to produce a light gray scar over the focal RPE leak. Typically, 6–12 laser burns of 50–200  $\mu$ m spot size at  $\leq 0.1$ -second duration and power ranging from 75–200 milliwatts (mW) are used. Permanent RPE change is induced at the site of the laser scar.<sup>4</sup> There have been reports of CNV after the use of laser photocoagulation, and EDI-OCT shows the continued presence of a thickened choroid. The only definite benefit from laser therapy is its ability to decrease the duration of the neurosensory detachment.<sup>61</sup> However, there are other reports showing that it neither affects the recurrence rate nor improves the final visual acuity or progression to chronic CSCR.<sup>62</sup>

Complications from laser photocoagulation include CNV and central scotoma. Although rare, they can be visually devastating (Fig. 6.31.8). Complications may be reduced by using larger spot sizes, employing lower power, and avoiding the capillary-free zone.<sup>4</sup> The rapid development of a choroidal neovascular membrane after laser photocoagulation suggests the possibility of an initial misdiagnosis and the likely presence of a pre-existing CNVM.<sup>63,64</sup>

PDT has been increasingly used to treat CSCR over the past decade. It is reportedly effective for both chronic CSCR (defined as  $>6$  months' duration of disease) with diffuse decompensation of the RPE lacking focal FA leaks,<sup>5–11</sup> and acute CSCR with focal RPE leaks.<sup>12,13,65</sup> PDT appears to be a more effective treatment with a lower complication rate for patients with subfoveal or juxtafoveal leaks. Using EDI-OCT, the choroid can be monitored to see if it thins after treatment with PDT.<sup>13</sup>

## COURSE AND OUTCOME

Generally, the visual prognosis for patients with CSCR is good.<sup>66</sup> Most patients suffer no significant permanent visual loss. In a series of 34 eyes with CSCR followed up for an average of 23 months without treatment,<sup>26</sup> visual acuity was no worse than 20/40 in any eye. This was despite large serous retinal detachments, multiple RPE leaks, cystoid macular changes, persistent RPEs, and marked visual loss during acute episodes. The persistent Amsler's grid changes present in 24 of 27 eyes were described as visually insignificant and causing no difficulty.<sup>67</sup> Although visual acuity usually improves, patients may continue to have persistent metamorphopsia probably because of photoreceptor misalignment causing a Stiles-Crawford effect. Rarely, CSCR can produce significant visual damage; usually caused by the chronic form of the disease.<sup>68</sup> RPE atrophy, drusen, and CNV have also been described in eyes with chronic CSCR.<sup>28</sup>

Follow-up FA of eyes with CSCR suggests that in certain patients, CSCR may herald a bilateral progressive RPE disturbance known as *chronic CSCR*.<sup>69</sup> Whether a history of CSCR exacerbates the natural course of AMD remains unresolved. However, recent studies suggest that CSCR in older individuals is more frequently associated with the formation of CNV compared with that in younger patients.<sup>22</sup>

**Fig. 6.31.8 Chronic Central Serous Chorioretinopathy With Choroidal Neovascular Membrane.** (A) Fundus photograph with central retinal pigment epithelium (RPE) changes and subretinal hemorrhage. (B) Spectral-domain optical coherence tomography (SD-OCT) showing subretinal fluid, retinal pigment epithelial detachments (RPED), and thickened choroid. (C) optical coherence tomography angiography (OCTA) at the choriocapillaris level reveals a tangled lesion consistent with a neovascular network. (Courtesy West Coast Retina.)

# Macular Hole

Andrew A. Moshfeghi, Christos N. Theophanous, Jay S. Duker

# 6.32

**IN THIS CHAPTER**  
Additional content  
available online at  
[ExpertConsult.com](http://ExpertConsult.com)

**Definition:** A full-thickness defect in the neural retinal concentric on the fovea.

## Key Features

- Central scotoma with or without metamorphopsia.
- Round, central neural retinal tissue defect.
- Perifoveal cystic retinal edema.
- Yellow spots in the base of the macular hole.
- Surrounding cuff of subretinal fluid.

## Associated Features

- Attached posterior hyaloid initially and can remain even after full-thickness hole develops.
- Epiretinal membrane (commonly).
- Occasionally bilateral (10%–20%), but typically sequentially, not generally with simultaneous onset.
- Simultaneous retinal detachment, rarely, especially in cases of pathological myopia, prior blunt ocular trauma, or chronic cystoid macular edema.

## INTRODUCTION

Until the 1990s, ophthalmologists paid little attention to macular holes because the pathogenesis was obscure and cure impossible. Our understanding of the pathogenesis of macular holes has evolved significantly over the past 2 decades, resulting in the development of a new classification that accounts for premacular hole clinical appearances and gives insight into macular hole formation.<sup>1</sup> In addition, optical coherence tomography (OCT) is now widely available for diagnosis and treatment planning.<sup>2</sup> Surgery helps reverse the visual loss in most cases.<sup>3,4</sup>

## EPIDEMIOLOGY AND PATHOGENESIS

Most full-thickness macular holes are idiopathic but can also form immediately after blunt ocular trauma and numerous rare entities.<sup>5-8</sup>

Macular hole is a rare condition occurring in approximately 1 in 500 patients, most commonly healthy individuals in their sixth or seventh decade of life.<sup>8,9</sup> Women are affected more commonly compared with men by a 2:1 ratio. About 10%–20% of cases eventually are affected bilaterally, but rarely simultaneously.<sup>8,9</sup>

The best available data suggest that abnormal tractional forces of the vitreous on the macula are directly responsible for the pathogenesis of idiopathic macular hole. This can be observed clinically with contact lens examination, ultrasonography, or, most reliably, with OCT.<sup>2</sup> The success of vitreous surgery for macular holes provides strong evidence for a direct role of the vitreous in its pathogenesis.<sup>3</sup>

## OCULAR MANIFESTATIONS

The hallmark complaint of idiopathic macular hole formation is painless development of central visual distortion or blur of an acute or subacute nature. When only one eye is involved, it is not unusual for the visual loss

to go undetected in the affected nondominant eye unless cross-covering is performed. Central visual acuity initially may be diminished only mildly; however, as the hole progresses, the acuity usually deteriorates commensurate with increasing hole diameter, then stabilizes around the 20/200–20/800 (6/60–6/240) level.

The Gass classification system explains the clinically observed appearance of macular holes in four stages and their precursor lesions. The hallmark inciting event of idiopathic macular hole formation is hypothesized to be focal shrinkage of the vitreous cortex in the foveal area.<sup>1</sup> Although Gass' clinical interpretations of the various stages are accepted widely, OCT classification studies imply that the retinal changes that occur in stage 1 holes differ slightly from his clinical classification.<sup>1</sup>

Foveal photoreceptor loss may occur in some cases, although a true retinal operculum rarely is evident. The central scotoma that results from foveal dehiscence is made significantly larger by the surrounding localized retinal detachment. Cystic changes develop in the intact perifoveal retina, and some eyes develop epiretinal membranes. All the factors combine to decrease the central vision. Rarely, rhegmatogenous retinal detachment beyond the macula occurs directly as the result of a macular hole only if abnormal vitreous traction or high myopia with staphyloma is present concurrently. Not uncommonly, idiopathic full-thickness macular holes may be observed during vitrectomy surgery for repair of rhegmatogenous retinal detachment resulting from a peripheral causative retinal break. In addition, macular holes have been observed subsequent to successful repair of rhegmatogenous retinal detachment that was not originally related to a full-thickness macular hole or after previous vitrectomy surgery.<sup>5,6</sup> The pathogenesis in these atypical cases is not entirely understood.

The Gass classification of macular holes is based on slit-lamp biomicroscopy of the retina rather than OCT findings, which had not yet been invented.

## Gass Stage 1 Macular Hole

In a stage 1 macular hole, no true neural retinal defect is present, the photoreceptor layer is intact, and no vitreofoveal separation has occurred. Oblique vitreofoveal traction is responsible and can be observed on OCT. Stage 1 holes are clinically subdivided into stage 1a (small central yellow spot is seen ophthalmoscopically) and stage 1b (a yellow foveal ring is observed).<sup>1</sup> They are typically asymptomatic and spontaneously resolve in half the cases.

## Gass Stage 2 Macular Hole

Progressive shrinkage of the perifoveal vitreous cortex in stage 1 eyes leads to stage 2 holes, which are small (100–300  $\mu$ m), full-thickness neural retinal defects (Figs. 6.32.1 and 6.32.2). Visual acuity is diminished, usually between 20/50 (6/15) and 20/400 (6/120), and a pseudo-operculum with condensed vitreous may be present. Once a stage 2 hole occurs, it typically progresses irreversibly to stage 3.

## Gass Stage 3 Macular Hole

Continued vitreofoveal traction results in a stage 3 hole with the classic macular hole appearance. This consists of a round, 350–600  $\mu$ m full-thickness neural retinal defect with smooth edges, and a small, surrounding, doughnut-shaped cuff of subretinal fluid with persistent hyaloid

**Fig. 6.32.1** Gass stage 2 macular hole. Clinical photograph demonstrating a cuff of subretinal fluid.

**Fig. 6.32.2** Gass stage 2 macular hole. Spectral-domain optical coherence tomography demonstrates a full-thickness neural retinal defect and an attached posterior hyaloid at the fovea and optic nerve.

attachment. With time, alterations in the retinal pigment epithelium (RPE; pigmented demarcation line) may develop at the leading edge of the subretinal fluid cuff. Visual acuity typically is between 20/200 (6/60) and 20/800 (6/240).

### Gass Stage 4 Macular Hole

A stage 4 macular hole has all the features of a stage 3 hole, but with complete posterior separation of the vitreous from the fovea. Yellow deposits can be seen in the base of the defect, and perifoveal cystic retinal changes are present (Fig. 6.32.3).

A newer classification of vitreoretinal interface disorders, including macular holes, has been developed based on OCT findings and hole size rather than clinical symptoms or observation, as discussed below.<sup>10</sup>

#### Vitreomacular Adhesion

Vitreomacular adhesion represents a stage of partial, perifoveal separation of the vitreous without other retinal changes. Vitreous attachment is visible within a 3-mm radius of the fovea. Adhesions may be further described as small ( $\leq 1500 \mu\text{m}$ ) or large ( $> 1500 \mu\text{m}$ ). These patients generally do not experience any visual changes.

#### Vitreomacular Traction

With excessive traction, vitreomacular adhesions can lead to retinal changes observed on OCT, such as alteration of the foveal surface, intraretinal

**Fig. 6.32.3** Clinical photograph of a Gass stage 4 macular hole with large basal hole diameter, large cuff of subretinal fluid, and drusen present at the base of the hole.

pseudocyst formation, or separation of the fovea from the RPE. These eyes represent vitreomacular traction (VMT), and patients typically report distorted or diminished vision. These holes may similarly be divided into small ( $\leq 1500 \mu\text{m}$ ) or large ( $> 1500 \mu\text{m}$ ) based on size of vitreous attachment. VMT is equivalent to a Gass Stage 1 macular hole.

### Full-Thickness Macular Hole

Full-thickness macular holes consist of disruption through all neural layers of the retina. The edges typically appear rounded because of the presence of subretinal fluid. These holes are subdivided by size (small:  $\leq 250 \mu\text{m}$ ; medium:  $> 250$ – $\leq 400 \mu\text{m}$ ; and large:  $> 400 \mu\text{m}$ ), presence or absence of vitreomacular traction, and cause (primary: caused by macular traction, secondary: caused by other pathology).

### Lamellar Macular Hole

A lamellar macular hole may represent an aborted macular hole. A round central inner retinal defect is observed, with no thickening, cystic change, or subretinal fluid. No full-thickness neural retinal defect is appreciated on OCT. An overlying retinal operculum is common. Vitreofoveal separation occurs with loss of the inner retinal layers; however, the outer, photoreceptor layer is intact. The vision typically remains good, and there is low risk of progression to macular hole.

### Pseudo-Macular Hole

A lamellar hole is to be distinguished from a pseudo-macular hole, which may appear ophthalmoscopically as a macular hole, but OCT reveals intact neural retina along with an opening in a dense overlying epiretinal membrane.

### “Stage 0” Macular Hole

One study suggests that abnormal vitreofoveal traction observed on OCT in the fellow eye of a patient with a macular hole is associated with an elevated risk (43%) of macular hole formation in the fellow eye. Fellow eyes without this abnormal vitreofoveal traction on OCT had a very low risk of subsequent macular hole formation.<sup>11</sup>

## DIAGNOSIS AND ANCILLARY TESTING

The diagnosis of idiopathic macular hole is clinical, made at the slit lamp with a macular lens, used in either a contact or noncontact fashion. At times, the purely clinical diagnosis can be difficult, especially when a unilateral stage 1 or stage 2 hole is present.<sup>12,13</sup>

Fluorescein angiography (FA) is not generally of benefit, although it can help to rule out other entities that mimic macular hole. In stage 1 macular

**BOX 6.32.1 Differential Diagnosis of Macular Hole**

Epiretinal membrane with macular pseudo-hole  
 Cystoid macular edema  
 Vitreomacular traction without full-thickness macular hole  
 Foveal drusen  
 Choroidal neovascular membrane  
 Central areolar pigment epitheliopathy  
 Pattern dystrophy  
 Solar retinopathy  
 Central serous chorioretinopathy  
 Lamellar (aborted) macular hole  
 Choroiditis

holes, FA commonly is normal or may variably reveal a window defect. The slit-beam test (Watzke–Allen sign) usually is reliable to test subjectively for a full-thickness retinal defect associated with a central absolute scotoma in response to a thin, vertically oriented slit beam focused on the macula. Cross-sectional imaging of the retina with OCT is used to confirm the diagnosis and to assess the attachment of the vitreous to the fovea.<sup>1,12,14</sup> OCT is, by far, the most clinically useful ancillary test. With spectral-domain, high-resolution OCT,<sup>14</sup> in addition to individual raster lines, the physician can also scroll through a digital cube of sampled retina and recreate a three-dimensional view of the vitreoretinal interface. This aids in surgical planning to see precisely where the posterior hyaloid or possible associated epiretinal membrane may be exerting perifoveal tension.

**DIFFERENTIAL DIAGNOSIS**

Macular holes may be confused with epiretinal membrane, cystoid macular edema, or vitreomacular traction (Box 6.32.1).

**PATHOLOGY**

Histopathology shows a round, full-thickness defect through all neural retinal layers. The underlying RPE is intact. Associated intraretinal edema and perifoveal photoreceptor atrophy are common. Epiretinal membrane formation is also common. Fibroglial proliferation across the retinal defect has been observed in pathology specimens from autopsy eyes of patients with closed macular holes.<sup>15</sup>

**TREATMENT**

Prior to 1989, idiopathic macular holes were considered untreatable. Kelly and Wendel<sup>3</sup> were the first to report that vitreous surgery can improve the visual acuity in some eyes with acute, idiopathic macular holes. Since then, vitrectomy for idiopathic macular holes rapidly has become a widely performed procedure throughout the world.

Gass stage 1 holes (VMT) are initially observed for three reasons:

- They have a 50% rate of spontaneous improvement.
- Surgical intervention does not prevent full-thickness macular hole formation universally, and intraoperative macular hole can occur.
- Vitrectomy for a Gass stage 2 hole of recent onset has a very high (>90%) anatomical success rate.

If a Gass stage 1 hole has significantly decreased visual acuity that persists for months, surgery may be considered.<sup>16</sup> Macular hole surgery (Video 6.32.1) typically is performed with the patient under local anesthesia on an outpatient basis. A standard three-port core vitrectomy is completed. Then, the adherent posterior cortical vitreous is engaged, typically by using the aspiration aspect of the vitrectomy instrument, with the cutting function disabled. The attached posterior hyaloid is usually invisible until it is elevated off the retina. Elevation of the cortical vitreous and posterior hyaloid is carried out until complete separation of the vitreous is achieved, and then it is consumed with the vitrector. Care is taken to avoid the crystalline lens in patients with phakia by using an alternate hand vitrectomy. Epiretinal membrane, if present, is peeled by using a bent, sharp needle, a diamond dusted soft-tipped membrane scraper, or fine internal limiting membrane (ILM) forceps. If ILM peeling is felt to be beneficial, it is performed at this stage. The internal limiting membrane can be stained with diluted indocyanine green (ICG) dye, dilute triamcinolone acetate, trypan blue, or brilliant blue to facilitate its surgical removal. An air–fluid exchange follows and air, sulfur hexafluoride (SF<sub>6</sub>) gas (20%–30%), perfluoropropane

(C<sub>3</sub>F<sub>8</sub>) gas (10%–18%), or silicone oil is injected into the vitreous cavity at the conclusion of the case. Patients usually are instructed to maintain strict face-down positioning for 1–7 days postoperatively, although recent reports have described comparable anatomical success rates for macular hole closure with zero face-down positioning.<sup>17</sup>

Greater than 50% of phakic eyes that undergo vitrectomy for a macular hole suffer significant nuclear sclerotic cataracts during the 2-year follow-up, and these can later be removed with standard cataract surgical techniques without undue risk.

Retinal tears, retinal detachment, or both may be seen in up to 10% of eyes that undergo macular hole repair. This incidence is relatively high because of intraoperative traumatic creation of posterior vitreous detachment in the critical step of the procedure.<sup>18</sup>

Less common complications include: intraoperative light; chemical or mechanical toxicity to the macular RPE; and intraoperative enlargement of the macular hole.<sup>18–20</sup> Late reopening occurs in 5% of successfully treated holes and can occur years later.<sup>20</sup> Successfully closed macular holes can reopen after YAG (yttrium–aluminum–garnet) laser capsulotomy or secondary cataract extraction. Therefore, contemporaneous creation of mechanical capsulotomy in patients with pseudophakia or cataract extraction in patients with phakia at the time of macular hole repair has been advocated by some.<sup>21</sup> Peeling of the ILM may decrease the rate of late reopening. Dense, temporal visual field defects have been observed in eyes that have undergone macular hole repair.<sup>22</sup> Intraoperative damage to the nerve fiber layer by either excessive desiccation secondary to air infusion and/or possible toxicity of ICG have been suggested, but adjuvant use of ICG is still common.<sup>23</sup> ICGA can be used under fluidic conditions for 30–45 seconds and then removed with the vitrector, with staining of the ILM posteriorly. In patients with an intact posterior lens capsule, use of ICG under fluidic conditions can also create staining of the posterior lens capsule. Care should be taken to avoid prolonged and direct light pipe illumination of the macular region while ICG is in the eye because this dye does have a photodynamic effect.<sup>23</sup>

Case-series reports have demonstrated that pneumatic vitreolysis (also referred to as “pneumatic maculopexy”) may also be a viable surgical option for the treatment of macular holes. Intravitreal injection of SF<sub>6</sub> or C<sub>3</sub>F<sub>8</sub> induces posterior vitreous detachment and can relieve traction on the retina.<sup>24,25</sup> The precise mechanism through which the procedure induces vitreous detachment is unknown, although it likely relates to liquefaction of the vitreous or expansion of existing vitreous pockets from expansion and contraction of the gas bubble. In a retrospective study of 15 eyes with stage 2 macular holes, two thirds achieved hole closure.<sup>25</sup> Although not studied in large trials, pneumatic vitreolysis may represent an alternative, lower cost surgical treatment for macular holes.

Recently, a less invasive approach for idiopathic full-thickness macular hole management has been described.<sup>26</sup> Following a single intravitreal injection of recombinant microplasmin enzyme (ocriplasmin; Thrombogenics, Inc., Leuven, Belgium), approximately 41% of 153 patients with a Gass stage 2 idiopathic full-thickness macular hole experienced successful hole closure without vitrectomy surgery compared with 17% of patients injected with a saline placebo.<sup>27</sup> In phase III studies, 30% of patients with macular hole achieved full closure following ocriplasmin injection compared with 15% of sham injection controls.<sup>28</sup> This closure rate was reached by 3 months after injection and held steady through 2 years of follow-up. Generally, adverse events were mild and transient, occurring within the first week after injection. Vitreous floaters, photopsia, and abnormal color vision tests are the most common adverse events, each occurring in approximately one third of patients. More serious adverse events, such as retinal breaks or detachments, were comparable between the treatment and control groups, therefore likely attributable to natural disease progression.<sup>28</sup>

**COURSE AND OUTCOME**

Stage 1 holes have a spontaneous rate of resolution of about 50%. Once a stage 2 hole occurs, visual loss is permanent without surgery. Spontaneous closure of full-thickness macular holes occurs in 2%–4% of eyes.<sup>8</sup>

Without surgery, macular holes tend to stabilize with a visual acuity of 20/200–20/800 (6/60–6/240) and a diameter of about 500  $\mu$ m. Anatomical success can be determined 2–4 weeks after surgery. Anatomical success usually is now defined with OCT as the reapproximation of retinal tissue covering the full-thickness defect. In most instances, when this occurs, the edges of the macular hole are apposed firmly to the RPE, which renders identification of the original location of the hole difficult (Fig. 6.32.4). In their initial series of 52 eyes, Kelly and Wendel<sup>3</sup> found that 42% showed a visual

**Fig. 6.32.4** Gass stage 4 macular hole. Postoperative spectral-domain optical coherence tomography appearance of a successfully closed macular hole with slowly resolving subfoveal fluid.

acuity improvement of  $\geq 2$  Snellen lines following surgery. Recent studies confirm that high rates of anatomical success (85%–100%) are achievable in large series of macular holes of all stages treated with vitrectomy, with approximately two thirds of eyes achieving 20/50 or better vision.<sup>29,30</sup> Initially, successful closure of the neural retinal defect may be observed in the presence of persistent subfoveal fluid (Fig. 6.32.5). The patient may have excellent visual acuity despite this persistent fluid or may complain of a persistent area of blurred vision. This may persist for months, but as the fluid is slowly reabsorbed, improved visual function can be observed.<sup>31</sup> Although 20/20 vision can be measured in many patients who had good presenting visual acuity, these patients may still report subtle imperfections in their central vision. Recent findings from spectral-domain OCT research suggest that a disruption in the inner segment/outer segment photoreceptor junction in eyes with closed macular holes may lead to a poorer visual prognosis compared with those with an intact inner junction.<sup>32</sup> Historically, very large Gass stage 4 macular holes (diameter >600 microns), were felt to be best left without surgical intervention, but recent reports have reported some anatomical and visual improvements with the use of the inverted ILM flap technique, in which a pedunculated flap of ILM is purposefully left over the macular hole just prior to the fluid–air exchange to serve as a scaffold to facilitate macular hole closure.<sup>33</sup>

**Fig. 6.32.5** Left column (top to bottom) demonstrates the intraoperative clinical (A) and intraoperative optical coherence tomography (OCT) appearance on horizontal (B) and vertical (C) scans of a Gass stage 1 macular hole demonstrating persistent vitreomacular traction <1500  $\mu\text{m}$ . Middle column demonstrates the intraoperative clinical appearance (D) of the posterior hyaloid as it was being elevated over the macula (arrows point to the posterior hyaloid face being elevated with vacuum and provided by the vitrectomy handpiece along with manual countertraction) with resultant release of traction. Right column (top to bottom) demonstrates the intraoperative clinical (E) and intraoperative OCT appearance on horizontal (F) and vertical (G) scans after traction is released. [ExpertConsult.com](http://ExpertConsult.com)

**Definition:** An avascular, fibrocellular membrane that proliferates on the inner surface of the retina to produce various degrees of macular dysfunction.

## Key Features

- Transparent, translucent, opaque, or pigmented membrane on the inner retinal surface.
- Tangential traction on the macula.
- Partial or complete posterior vitreous separation.

## Associated Features

- Central vision loss with or without metamorphopsia.
- Glistening light reflex.
- Retinal distortion.
- Macular edema.
- Retinal whitening (axoplasmic stasis).
- Intraretinal or preretinal hemorrhage.
- Macular hole or pseudo-hole.

## INTRODUCTION

The proliferation of fibrocellular membranes on the inner retinal surface in the macular area may occur in otherwise healthy eyes or secondary to retinal breaks and rhegmatogenous retinal detachment, retinal vascular diseases, intraocular inflammation, blunt or penetrating trauma, and other ocular disorders. Common synonyms applied to epiretinal membranes (ERMs) include macular pucker, premacular fibrosis or gliosis, cellophane maculopathy, surface wrinkling retinopathy, and epimacular membrane. Visual symptoms associated with ERMs range in severity, depending on the opacity of the membrane and the amount of macular distortion induced by the contracting fibrocellular tissue. Surgical peeling of ERMs in patients who have significant visual symptoms typically results in improved visual acuity and reduced metamorphopsia.

## EPIDEMIOLOGY AND PATHOGENESIS

The majority of patients who have idiopathic ERMs are age >50 years; however, children and young adults occasionally are affected.<sup>1,2</sup> The prevalence of idiopathic ERMs diagnosed with color fundus photography in population-based studies ranges from 4%–11%.<sup>3–5</sup> The prevalence may be significantly higher in certain racial groups, particularly Hispanics.<sup>6</sup> Autopsy studies demonstrate a similar prevalence, approximately 6%, with increasing prevalence in advancing age groups.<sup>7,8</sup> Many large series suggest a higher prevalence of epiretinal formation in women than in men.<sup>1,9–11</sup> Although idiopathic ERMs are bilateral in 20%–30% of cases,<sup>1,3,7</sup> significant bilateral loss of central vision is uncommon.

The 5-year incidence of idiopathic ERM formation is approximately 5%.<sup>12</sup> Incident ERMs are more commonly mild cellophane maculopathy (5-year incidence of 3.8%) compared with premacular fibrosis with retinal striae (5-year incidence of 1.5%). The incidence of epiretinal formation is higher in patients with an ERM in the fellow eye at baseline (5-year

incidence of 13.5%).<sup>12</sup> The incidence of symptomatic epimacular membrane formation is 4%–8% after repair of rhegmatogenous retinal detachment,<sup>13–15</sup> and 1%–2% after prophylactic treatment of peripheral retinal breaks.<sup>16</sup> Risk factors for the development of macular ERMs after conventional retinal detachment surgery include older age, preoperative vitreous hemorrhage, macular detachment, preoperative signs of proliferative vitreoretinopathy, large retinal breaks, intraoperative use of cryotherapy, and multiple operations.<sup>13–15,17</sup>

Mild ERM formation occurs commonly in association with blunt or penetrating ocular trauma, vitreous inflammatory conditions, retinal vascular diseases that cause chronic intraretinal edema, and long-standing vitreous hemorrhage.<sup>17,18</sup> Apart from penetrating trauma, these are uncommon clinical contexts in which to find significant macular dysfunction as a result of ERM contracture.

The pathogenesis of ERMs is not completely understood. It appears that the pathogenesis of idiopathic ERMs may differ from that of ERMs occurring after retinal detachment. The development of posterior vitreous detachment appears to be central to the development of idiopathic ERMs.<sup>19</sup> It has been observed that a clinically detectable posterior vitreous detachment is present in approximately 90% of eyes that have idiopathic membranes.<sup>1,10,20–22</sup> Vitreoretinal traction that occurs during the development of a posterior vitreous detachment may create defects in the internal limiting membrane (ILM) that allows migration of retinal glial cells and subsequent proliferation and contraction on the inner retinal surface.<sup>7,23,24</sup> An alternative, and more likely, proposed mechanism for idiopathic ERM formation involves proliferation, fibrous metaplasia, and contraction of hyalocytes left behind on the inner retinal surface after posterior vitreous detachment.<sup>17</sup> Previous studies have reported that 10%–25% of ERMs occur in the absence of a posterior vitreous detachment, suggesting that cellular migration may sometimes occur through pre-existing defects or thinning in the ILM.<sup>25</sup> More recent investigations utilizing ultrasonography and optical coherence tomography (OCT) demonstrate that in eyes with an ERM but without a complete posterior vitreous detachment (PVD), a partial, perifoveal PVD is invariably present<sup>19,26</sup> (Fig. 6.33.1).

ERMs that develop in eyes that have retinal breaks most likely represent a mild form of proliferative vitreoretinopathy caused by retinal pigment epithelium (RPE) cells that are liberated into the vitreous cavity

**Fig. 6.33.1 Epiretinal Membrane Associated with Partial Perifoveal Vitreous Detachment (PVD).** Optical coherence tomography imaging demonstrates a shallow detachment of the posterior hyaloid from the macular region in this eye with epiretinal membrane and no biomicroscopic evidence of PVD.

and proliferate, along with other cellular constituents, to form contractile membranes on the retinal surface.<sup>27</sup> Cellular proliferation stimulated by vitreous inflammation or breakdown of the blood–retinal barrier is a plausible pathogenic mechanism for the remaining types of secondary ERMs.

The pathogenesis of visual loss secondary to an ERM remains poorly understood. Theoretical mechanisms of visual loss include a filtering effect of the ERM on the photoreceptors, mechanical distortion of the photoreceptors, obstruction of axoplasmic flow, intraretinal edema, or alterations in macular blood flow. Multifocal ERG studies of patients with idiopathic ERMs demonstrate larger b-wave depression suggesting that the original site of dysfunction is located within the inner retina with photoreceptor dysfunction being a later phenomenon.<sup>28</sup> The biphasic first order response of the multifocal ERG includes an initial negative deflection (N1) followed by a positive peak (P1). The P1 response may include contribution of the Müller and bipolar cells. In one series of idiopathic ERM cases undergoing surgery, the P1 response was shown to be more predictive of final visual outcome than the N1 response reflective of the photoreceptor dysfunction.<sup>29</sup> In this series, only 27% of the patients with poor visual outcomes postoperatively had normal P1 times preoperatively, yet 53% showed no evidence of disruption of the inner segment/outer segment (IS/OS) junction on spectral-domain OCT (SD-OCT) indicative of photoreceptor damage. This again suggests that Müller/bipolar cell dysfunction induced by an ERM may precede photoreceptor dysfunction.

## OCULAR MANIFESTATIONS

The symptoms of an ERM are largely determined by the thickness of the ERM and the degree of its contracture. In its mildest form, often called “cellophane maculopathy,” the membrane is thin and transparent, produces no distortion of the inner retinal surface, and leaves the patient asymptomatic. With more significant contraction of the membrane, full-thickness distortion, folding, or puckering of the macula typically results in complaints of metamorphopsia, loss of visual acuity, and occasionally central photopsia. In some patients, an eccentrically located ERM may cause lateral displacement of the fovea without detachment from the pigment epithelium (foveal ectopia); this results in relative preservation of visual acuity and symptoms of central binocular diplopia. Other patients who have ERMs that do not result in severe acuity loss complain of macropsia, presumably because of the crowding of photoreceptors caused by tangential retinal traction and thickening in the inner nuclear layer.<sup>30</sup>

The diagnosis of ERMs is primarily clinical, based on biomicroscopic observation. Contact lens biomicroscopy frequently is helpful in the detection of subtle transparent or translucent ERMs, particularly in eyes that have corneal surface irregularities or media opacities. Furthermore, the excellent resolution and stereopsis afforded by the fundus contact lens permit detailed assessment of the extent to which the macula is distorted, thickened, displaced, or detached by the membrane. Detection of subtle membrane edges by contact lens examination may help plan the surgical approach.

The mildest form of ERM may present only an abnormal glistening light reflex from the inner retinal surface (Fig. 6.33.2). Thin membranes that have undergone limited contraction or shrinkage produce a series of fine, irregular striations or wrinkles that are confined to the ILM and inner retinal tissue. The inner retinal striae typically are most apparent where they radiate out from the margins of the membrane but also may develop in a radiating pattern around one or more epicenters of membrane contraction. The fine macular capillaries may be tortuous, even in the absence of large vessel displacement. Thicker, more contracted ERMs produce tangential traction on the full-thickness neural retina, which results in more severe degrees of macular dysfunction. The membrane itself may remain largely invisible despite significant underlying retinal vascular tortuosity or straightening (Fig. 6.33.3). In other cases, the membrane is visible as a gray-white translucent membrane that partially obscures visualization of retinal vessels (Fig. 6.33.4). Some membranes, particularly those that develop subsequent to retinal breaks or rhegmatogenous retinal detachment, are thick and opaque, usually white in color, but occasionally darkly pigmented. Often a significant component of the membrane’s apparent opacity is whitening of the inner retina that underlies the membrane; presumably this results from traction-induced axoplasmic stasis in the nerve fiber layer (Fig. 6.33.5). The tractional effects of the membrane on the retina may cause macular edema, preretinal or intraretinal hemorrhage (Fig. 6.33.6), or traction macular detachment. Traction-induced detachments of the macula may be subtle, shallow, “tabletop” elevations visible only by contact lens biomicroscopy, or obvious ridges of detachment that pass through the macula. The presence of a defect in the prefoveal portion of

**Fig. 6.33.2 Mild Asymptomatic Epiretinal Membrane.** This thin transparent membrane is detectable only from an irregular, glistening (“cellophane”) light reflex from the inner retinal surface. The striae are well demonstrated on the red-free photo.

**Fig. 6.33.3** Transparent epiretinal membrane here seen to produce significant retinal vascular distortion.

an ERM may simulate the appearance of a full-thickness macular hole (Fig. 6.33.7). The appearance of a macular “pseudo-hole” is a result of the defect in the epiretinal tissue itself, as well as of the anterior and central displacement of the perifoveolar retina (clivus) during contraction of the ERM.<sup>17</sup> In some cases, a pseudo-hole also involves an inner lamellar macular defect that developed at the time of vitreofoveolar separation. Although it is an uncommon mechanism, tangential foveal traction from contraction of an eccentric ERM occasionally causes full-thickness macular hole formation. Unlike eyes that have true macular holes, those with pseudo-holes usually are minimally symptomatic and have normal or near-normal visual acuities. Biomicroscopic clues that help differentiate a macular pseudo-hole from a true macular hole include the following:

- Wrinkling of the inner retinal surface that surrounds the hole.
- Presence of retinal tissue in the base of the pseudo-hole.
- Absence of characteristic features of full-thickness macular holes, such as yellow RPE deposits in the base of the hole, a halo of neural detachment, and an overlying operculum or pseudo-operculum.

The Watzke–Allen (slit-beam) or laser aiming beam tests may occasionally help to differentiate a macular pseudo-hole from a full-thickness macular hole that complicates an ERM. In equivocal cases, OCT can

**Fig. 6.33.4 Typical Appearance of Gray-White Translucent Epiretinal Membrane.** Note the partially obscured, distorted retinal vessels and multiple inner retinal striae.

**Fig. 6.33.7 Epiretinal Membrane With Macular Pseudo-Hole.** The visual acuity is 20/25 (6/8) and slit-lamp biomicroscopy shows retinal tissue in the base of the apparent macular hole.

**Fig. 6.33.5 Severe Macular Puckering by an Opaque Epiretinal Membrane After Retinal Detachment Surgery.** Much of the apparent opacity is caused by inner retinal whitening from axoplasmic stasis.

**Fig. 6.33.6 Preretinal hemorrhage induced by traction from an epiretinal membrane.**

distinguish between a full-thickness macular hole and a macular pseudo-hole.

Certain clinical features, although rare, can provide the clinician with clues that the ERM may be secondary to other ocular pathology or indicate a more guarded visual prognosis. Rarely, contracture of an ERM with a central dehiscence causes anterior prolapse of foveal tissue through the hole in the membrane.<sup>31</sup> Long-standing macular traction or retinal vascular leakage induced by ERMs may cause atrophic and/or hypertrophic RPE alterations. Such changes generally are considered poor prognostic signs for visual recovery after surgical removal of the ERM. Occasionally, intraretinal lipid (hard) exudates and/or microvascular changes, such as microaneurysms, are produced by the retinal vascular traction and leakage caused by idiopathic ERMs. Such findings, however, also may signal the presence of associated pathology, such as a choroidal neovascular membrane or long-standing branch retinal vein occlusion, which may require different management approaches and alter the visual prognosis.

## DIAGNOSIS AND ANCILLARY TESTING

The diagnosis of ERM is primarily clinical. Ancillary testing does play an important role in the evaluation of patients with ERMs. Imaging studies can provide important information when formulating a management plan, including excluding associated macular disease, particularly retinal vascular disease.

Examination and/or photography of the macula with red-free light may highlight glistening reflexes and thereby assist in assessment of the extent of the membrane. Fluorescein angiography (FA) is useful in the evaluation of patients with ERMs, particularly in eyes that have media opacities that preclude adequate macular examination. A typical fluorescein angiogram in a patient with an ERM will not demonstrate any significant late leakage (Fig. 6.33.8). In some cases, there may be minimal irregular, late intraretinal leakage in the macula. The distribution of leakage is usually determined by the location of the ERM. Although cystoid leakage is common, the fluorescein angiogram in a patient with an ERM can be differentiated from the more symmetrical cystoid pattern seen in pseudo-phakic cystoid macular edema. FA also may be valuable to assess the degree of retinal vascular distortion, confirm the presence of foveal ectopia, detect associated macular edema, differentiate pseudo-holes from full-thickness macular holes, and highlight underlying RPE changes. Finally, FA may be critical in the exclusion of associated macular pathology, such as choroidal neovascularization or venous obstructive disease (Fig. 6.33.9).

OCT has emerged as a useful, noninvasive tool for the evaluation of ERMs. ERMs appear as a hyperreflective band anterior to the retina. The majority of ERMs are globally adherent to the retinal surface, however, some appear to have focal adhesions.<sup>32</sup> These focal adhesions may be more common in eyes with secondary ERMs and may reflect differences in pathogenesis.<sup>32</sup> OCT is also useful in the differentiation of macular pseudo-holes from lamellar and full-thickness macular holes. Pseudo-holes typically have a visible gap in the hyperreflective ERM (Fig. 6.33.10). The

**Fig. 6.33.8 Fluorescein Angiogram of Patient With Idiopathic Epiretinal Membrane.** (A) Fluorescein angiogram without significant fluorescein leakage. (B) Horizontal spectral-domain optical coherence tomography demonstrating intraretinal cystoid changes.

**Fig. 6.33.9 Fluorescein Angiography of an Epiretinal Membrane That Complicates an Old Branch Retinal Vein Occlusion.** Note the collateral vessel formation, in addition to the marked vascular distortion.

**Fig. 6.33.10 Optical coherence tomography (OCT) of an epiretinal membrane with a central pseudo-hole.**

foveal thickness is near normal, whereas the parafoveal retina is thickened.<sup>32</sup> Lamellar holes are often observed to have medium, homogeneous, hyperreflective epiretinal proliferation that may coexist with typical ERM. This lamellar hole associated epiretinal proliferation is generally not associated with contractile effects in the retina and may be more common in larger, thinner lamellar holes.<sup>33</sup> OCT is also useful for confirmation of the presence of vitreomacular traction (Fig. 6.33.11). OCT may be predictive of visual outcome with ERM surgery.<sup>34</sup> The hyperreflective line above the RPE demonstrates the IS/OS junction of the photoreceptors (Fig. 6.33.12). Several studies have demonstrated that an intact, continuous IS/OS junction is predictive of better visual outcome at 12 months.<sup>29,35</sup> SD-OCT may provide better visualization of the IS/OS junction, particularly in the setting of inner retinal edema secondary to ERM.<sup>35</sup>

**Fig. 6.33.12 Optical Coherence Tomography (OCT) of Patient With Epiretinal Membrane Demonstrates Significant Surface Retinal Distortion and Inner Retinal Edema.** The outer retina is relatively unaffected, and the patient has 20/25 visual acuity.

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis of ERMs is given in Fig. 6.33.12. The most common diagnoses that must be differentiated from ERM and its associated features include the vitreomacular traction syndrome, postoperative cystoid macular edema, and full-thickness macular hole (as opposed to ERM with macular pseudo-hole). Such differentiations are important to make because each of these clinical entities (discussed in detail in the chapters listed) differ from ERM in their management and prognosis.

## PATHOLOGY

Histopathological and ultrastructural studies have shown that ERMs consist of a fibrocellular sheet of varying thickness, in which both native vitreous and newly synthesized collagen have been found.<sup>7,8,17,23-25,27,36,37</sup> Fragments of ILM are seen commonly in surgical specimens,<sup>37</sup> which suggests that the inadvertent or intentional removal of this membrane does not preclude good visual outcomes.

The cellular elements of most ERMs include one or more of the following: RPE cells, fibrous astrocytes, fibrocytes, and macrophages. The cell types found in a particular membrane may depend, in part, on the associated ocular disorders.<sup>7,27,36,37</sup> Furthermore, the precise identification of the cells of origin within ERMs is hampered by the ability of each of the common constituent cells to transform into cells with similar morphology

and function.<sup>17</sup> The observation that RPE cells are the main cell type in many cases of idiopathic ERM is poorly understood<sup>36</sup> but possibly may involve transretinal migration of RPE cells in response to biochemical stimuli.<sup>38</sup> Most of the cell types found in ERMs have the capacity to assume myofibroblastic properties, which allows them to change shape and cause the membrane to contract.<sup>17</sup> ERM formation in association with vitreomacular traction may differ slightly in pathogenesis, with histopathological studies demonstrating a strong predominance of myofibroblasts.<sup>39</sup> In addition, in this series, it was noted that patients with ERM associated with vitreomacular traction syndrome had a thin layer of remnant native vitreous collagen trapped between the cellular myofibroblast layer and the ILM. This suggests that the residual vitreous plays an important role in ERM development.<sup>39</sup> Soluble growth factors may influence cell migration in the development of ERM. Case-control studies of vitreous samples of LR11, a regulatory growth factor for adherent cells, have shown that LR11 is higher in cases of ERM with premacular fibrosis compared with those with cellophane maculopathy.<sup>40</sup>

## TREATMENT

Mild ERMs typically produce minimal symptoms. In many cases, no intervention is required. Population-based photographic studies of patients with ERMs show that patients with cellophane maculopathy rarely demonstrate progressive visual loss.<sup>12</sup> In the same study, patients with more significant premacular fibrosis and retinal striae appeared to be equally stable with little progression of the ERM or visual loss.<sup>12</sup> Because ERMs often show little or no progression after the initial diagnosis, surgery is not performed prophylactically on mild membranes.

Patients who have more severe membranes that produce significant visual loss and/or metamorphopsia usually benefit from vitreous surgery with peeling of the ERM from the surface of the macula. The goal of membrane peeling is to reduce or eliminate the most common mechanisms of visual loss, including macular distortion, traction macular detachment, foveal ectopia, tissue that covers the fovea, retinal vascular leakage with macular edema, and traction-induced obstruction of axoplasmic flow. In general, most patients considered for vitrectomy have significant visual impairment. In some cases, patients with significant visual symptoms but relatively preserved visual acuity may also benefit from surgery.<sup>41</sup> The best candidates for surgery are those who have membranes for a relatively short period because the potential for visual recovery decreases with increasing duration of preoperative symptoms.<sup>9</sup> However, excellent visual recovery is not necessarily precluded in patients who have symptoms that have lasted >1 year. Careful preoperative evaluation of all eyes should exclude additional causes of vision loss, such as choroidal neovascularization, macular ischemia from previous retinal vascular occlusion, or other pre-existing macular disease.

Conventional pars plana vitreous surgical techniques are used to remove the vitreous gel, which, in most cases, has separated previously from the posterior retina. A variety of techniques have been described to elevate and remove the ERM.<sup>42</sup> An edge of the ERM is engaged with a vitreoretinal pick or forceps or created with a sharp bent-tip needle. After developing an edge, the membrane is typically peeled from the retina with forceps, usually as a single piece. Rarely, sites of firm adhesion to the retina are encountered; at these, the membrane may be amputated in preference to the creation of retinal breaks in the macular area.

Several controversies exist in the surgical management of ERMs. In recent years techniques have been developed that allow removal of the ILM along with the ERM. In theory, removal of the ILM may reduce the chances of persistent or recurrent ERM. Several comparative studies confirm that ILM removal reduces the risk of recurrent or persistent ERM; however, no clear benefit to visual recovery has been demonstrated.<sup>43,44</sup> Identification of the ILM and, in some cases, the extent of the ERM can be difficult. Some vitreoretinal surgeons have advocated the use of vital dyes, such as indocyanine green (ICG), trypan blue, or brilliant blue G, to assist in these tasks. Although these adjuncts assist in surgical identification of the ILM and ERM, they have not clearly been demonstrated to improve the visual outcome.<sup>45-47</sup> In addition, there is some controversy regarding the potential toxicity of ICG dye.<sup>45,46</sup> Toxicity issues of ICG are not clearly understood, given that the dye concentrations, osmolalities, and exposure times have varied among studies.<sup>48</sup>

Of the patients undergoing vitrectomy, >75% will have improved visual acuity. Predictors of better visual outcomes include preoperative visual acuity better than 20/100, shorter duration of symptoms and absence of tractional retinal detachment.<sup>22</sup> Preoperative cystoid macular edema may be a poor prognostic sign.<sup>49,50</sup> Newer retinal imaging studies, including

OCT and multifocal-electroretinography (mERG), may also be predictive of visual outcome. Shorter P1 times appear to correlate with better final visual acuity.<sup>29</sup> Younger patients experience benefits similar to those of ERM surgery; however, the recurrence rate appears to be higher, approaching 25%.<sup>51,52</sup>

The most common surgical complication is progressive nuclear sclerotic cataract, which occurs in 60%–70% of eyes within 2 years after surgery, with a much lower incidence in patients age <50 years.<sup>11,53</sup> Other less common complications include peripheral retinal breaks, rhegmatogenous retinal detachment, posterior retinal breaks, photic maculopathy, and endophthalmitis. Late postoperative recurrence of symptomatic epiretinal tissue occurs in approximately 5% of patients.<sup>9,11</sup>

## COURSE AND OUTCOMES

Most patients who have ERMs experience little or no symptom progression after the initial diagnosis, which implies that membrane contraction usually occurs soon after its formation and then stabilizes. Only 10%–25% of eyes show a decline in visual acuity over time—rates of progression vary from over several months to many years.<sup>9,12,17</sup> Rarely, ERMs separate spontaneously from the retina, which results in visual improvement.<sup>17</sup> Approximately 20% of patients who develop macular pucker after scleral buckling experience spontaneous improvement in visual acuity, as a result of resolution of the macular edema and relaxation or partial peeling of the ERM.<sup>13</sup>

Following surgical removal of ERMs, most of the macular distortion and all of the retinal whitening resolves, typically within days or weeks of the operation (Fig. 6.33.13). Associated cystoid macular edema may resolve or persist chronically. Even in eyes that appear quite normal postoperatively, OCT typically shows some degree of persistent foveal thickening indefinitely (Fig. 6.33.14). Visual improvement of  $\geq 2$  Snellen lines occurs in 60%–85% of eyes and may continue for 6–12 months after surgery.<sup>9,11,22</sup> A small number of eyes (2%–15%) have worse visual acuity postoperatively.<sup>9,11,22</sup> (Video 6.33.1).

Although visual acuity improves and metamorphopsia is reduced significantly in most eyes after ERM peeling, the visual function rarely returns to normal. Studies of pre- and postoperative multifocal ERG shows an improvement in the oscillatory potentials, a- and b-waves, however, they rarely reach the levels of the unaffected fellow eye.<sup>28</sup> Patients commonly are advised to expect improvement in visual acuity that is approximately halfway between the preoperative acuity and normal. Preoperative factors prognostic of the final visual acuity include the level of preoperative visual acuity, duration of symptoms before surgery, and nature of previous macular damage, such as by retinal detachment involving the macula.<sup>11,50</sup> Eyes that have lower levels of preoperative visual acuity typically improve by the most number of lines but tend to have lower final acuities than eyes that had better preoperative vision.<sup>47</sup> Although the prognostic value of preoperative macular edema is controversial, FA probably does not help predict the visual outcome in patients who undergo surgery for idiopathic ERM.<sup>11,54</sup> OCT parameters may be better prognostic factors for

improvement in vision with vitrectomy. Lesser central foveal thickness at baseline, good integrity of inner/outer segment junction, and thinner ganglion cell/inner plexiform layer appear to be predictive of improvement.<sup>55</sup>

# Vitreomacular Traction

William E. Smiddy

# 6.34

**Definition:** Incomplete anomalous, posterior vitreous detachment with a varied degree of preretinal tissue proliferation and associated traction via a variably sized zone of persistent vitreous attachment is best diagnosed with optical coherence tomography.

## Key Features

- Distortion of the internal limiting membrane with retinal striae and vascular tortuosity.
- Intraretinal edema spaces associated with the vitreomacular attachment site.
- Possible localized traction-related macular detachment.

## Associated Features

- May manifest a “pseudo-macular hole” configuration clinically.
- Should be distinguished from vitreomacular attachment, which is most commonly a normal finding but may be a precursor form.

## INTRODUCTION

The interaction of the vitreous and macular surfaces may take on a variety of configurations. The extent and location of this interaction define a corresponding range of conditions, including full-thickness macular hole (FTMH), forms of lamellar macular hole, myopic traction maculopathy (MTM), cystoid macular edema (CME), epiretinal membrane (ERM), and vitreomacular traction (VMT).<sup>1-8</sup> These may be unified in the concept that they represent a family of conditions characterized by the spectrum of variations of anomalous posterior vitreous detachment (PVD).<sup>9</sup>

The moniker *vitreomacular traction syndrome* (VMTS) was originally coined on the basis of clinical, ophthalmoscopic findings of visibly persistent, variable extensive vitreous attachment at the macula associated with epiretinal proliferation,<sup>10-13</sup> essentially a macular pucker without complete PVD.

Optical coherence tomography (OCT) became available with increasingly finer resolution, and definitively revealed much more anatomical details than could be observed or even inferred clinically.<sup>14</sup> It has become the defining tool for what is now recognized as a host of macular conditions. Subsequently, a more subtle entity is now generally referred to by the same name—in this chapter, it will be referred to as VMT—as defined in accordance with the OCT features.<sup>15-18</sup> The VMT configuration is not rare, being present in about 2% of eyes.<sup>19</sup>

This chapter will focus on the contemporary entity of VMT, rather than the previously defined VMTS. The clinical embryogenesis of the current entity of VMT is closer to the impending (stage 1) macular hole entity, which was the focus of much attention in the late 1980s,<sup>20-23</sup> before the successes of macular hole surgery became apparent.<sup>24-30</sup> This similarity has been refined through OCT images.

OCT has verified that the posterior hyaloid may even split in such a way as to simulate a PVD, yet still maintaining a gossamer attachment posteriorly in VMT cases (Fig. 6.34.1). Now, as was the case with an impending

**Fig. 6.34.1** A 78-year-old woman with visual acuity of 20/30 OS (left eye) as a result of vitreomacular traction, but with only minimal metamorphopsia. The other eye is 20/200 with a macular scar. Optical coherence tomography shows gossamer attachment of the vitreous at the fovea, where distortion of inner retinal layers suggests traction. There was spontaneous resolution 2 months later.

macular hole, a treatment objective includes pre-emption to avoid formation of full-thickness macular hole and its incumbent visual loss. As will be discussed in the next section, only a minority of VMT cases progress to FTMH. Hence, the primary treatment objective in VMT cases with decreased visual acuity is to restore some of the lost vision. The ongoing conundrum is how to identify cases that are at highest risk to progress to further loss of vision or to FTMH formation. This uncertainty has hampered optimal application of the several treatment options that have now been developed.

## NATURAL HISTORY OF VITREOMACULAR TRACTION

A logical, even necessary, point of departure to bring some order to therapeutics is a better definition of the natural history so that therapeutic intervention can be optimally applied. Although randomized controlled trials may offer more definitive information, it is difficult to perform them from logistical, ethical, and study design perspectives. Hence, natural history studies, even if restricted to relatively milder cases, offer the best foundation available. It has been long recognized that spontaneous resolution may occur even among the more severe, clinically evident cases of VMT<sup>17,19,31,32</sup> (Fig. 6.34.2), but the earliest studies suggested frequencies of only ≈10%.<sup>33</sup> More recently published surveys, albeit of selected cases (generally milder degrees of vision loss), have demonstrated spontaneous resolution rates of OCT-defined cases as being ≈30%, and the rate of those not progressing has been up to 60%, depending loosely on the anatomical configuration.<sup>34,35</sup> Some attempts to grade the severity of the tractional effects have yielded the conclusion that, paradoxically, those with more severe tractional effects are the most dynamic—they have the highest risk

**Fig. 6.34.2** (A) Optical coherence tomography (OCT) of a 76-year-old man with visual acuity of 20/40 and central visual blurring. There is insertion of vitreous into the fovea with slight disruption of inner layers. (B) There was spontaneous resolution by a follow-up examination 6 weeks later and improvement to 20/25.

of progression but also the highest likelihood of spontaneous resolution. This further complicates optimizing treatment targeting.

## DIAGNOSIS AND ANCILLARY TESTING

Fastidious macular examination with fundus contact lens (or even suspended precorneal lens) at the slit lamp provides ideal visualization of the vitreomacular interface anatomy but does not offer as much objective detail as OCT. OCT demonstrates the characteristic vitreoretinal attachment and preretinal tissue better than any other imaging.<sup>15</sup> Lack of leakage on fluorescein angiography (FA) is characteristic of VMT; although this might complement the OCT diagnosis, it is rarely contributory, hence usually unnecessary.

## DIFFERENTIAL DIAGNOSIS

There are two aspects to differential diagnosis as they relate to VMT—determining the proper diagnosis as well as staging. Principally, OCT easily allows distinguishing VMT from an FTMH, lamellar macular hole, or an ERM—entities with different treatment objectives and even prognoses. Myopic traction maculopathy is less commonly confused with VMT, especially when taken in context.<sup>36,37</sup> Secondly, OCT characterizes or stages the process. The presence of an ERM and the extent of the vitreomacular attachment are important prognostic factors; the extent of any disruptions of deep retinal layers might be important as well. Moreover, it is important to verify that the symptoms or degree of visual loss is attributable to the anatomical derangement when considering treatment.

## PATHOLOGY

There are no histopathological studies of tissues removed from cases of VMT, but the inference from ongoing macular hole studies is that the tissue at, and adherent to, the foveal surface is composed of posterior hyaloid lamella and typical ERM or VMTS cellular elements.<sup>38,39</sup>

**Fig. 6.34.3** (A) A 71-year-old man with loss of central visual acuity to 20/70 for 6 weeks and prominent vitreomacular traction. Intravitreal ocriplasmin was tried, but there was no change in the appearance or symptoms after another month. (B) Vitrectomy with removal of the posterior hyaloidal attachment and peeling of the internal limiting membrane restored a foveal contour by 1 month postoperatively and visual acuity improvement to 20/40.

## TREATMENT

### Vitrectomy

The incomplete understanding of the natural history has not prevented investigation into treatment options. The immediate therapeutic objective is to release the vitreomacular tractional adherence. Currently, there are three interventional options to consider: vitrectomy, intravitreal ocriplasmin, and pneumatic vitreolysis.

Standard vitreous surgical techniques,<sup>40-48</sup> including removal of anterior-to-posterior traction, disinsertion or amputation of the vitreous insertion site at the fovea, and removal of preretinal tissue, are employed (Fig. 6.34.3). Although it is difficult to standardize cases within series, much less between series, the rate of visual improvement has been reported to range from 45%–91%.<sup>41,44-47</sup> (Video 6.34.1). The posterior hyaloidal attachment may be separated by using an adaptation of the en bloc approach, with incision through the posterior hyaloid paracentrally to offer a more controlled, monitorable release while minimizing the risk of unroofing the attenuated inner foveal layer. Alternatively, gentle suction on the posterior hyaloidal layer (as with a flexible tipped extrusion probe) so as to complete the PVD has been employed, but no comparative trial has been undertaken to define the optimal surgical method. The surgical anatomy may include an apparent “double layer” of (split) vitreous with or without preretinal cellular proliferation, probably correlating to a splitting of the posterior hyaloid (vitreoschisis), in contrast to the monolayer of preretinal tissue in standard macular pucker. Searching with a flexible tipped extrusion probe might allow detection of any residual “second” vitreous layer or, conversely, certify the presumption that all was effectively removed. Whether removal of internal limiting membrane (with or without the use of dyes) enhances outcomes is debated but is often pursued to verify that any preretinal mediator of traction has been eliminated, at least in cases where visually this seems to be cleavable at the fovea without inducing a macular hole. Similarly, the routine use of an intraocular gas bubble has not been established. Certainly, in cases where an FTMH is suspected to have occurred intraoperatively or if undue attenuation of the innermost foveal layer is suspected, this should be pursued. There is a substantial risk of postoperative macular hole formation, so this author has adopted a lower threshold for performing this procedure.<sup>48</sup>

See clip:  
6.34.1

**Fig. 6.34.4** (A) A 46-year-old woman with visual acuity of 20/30 but complaining of marked central metamorphopsia OD (right eye). There is a fine vitreomacular attachment and mild disruption of the inner layer, but also slight parting of the outer retinal layers. She had had macular hole surgery 2 years previously OS (left eye) with 20/30. Intravitreal ocriplasmin was injected. (B) There was still a pocket of subretinal fluid under the fovea 5 months later, and the patient was bitterly disappointed with deterioration of vision to 20/60 from postoperative week 1 onward. (C) Finally, 1 year after the injection, her visual acuity had improved to 20/20, and the foveal contour had normalized.

## Pharmacological Vitreolysis

Pharmacological weakening of the vitreomacular attachment has been more broadly sought for many years but has found application in the form of microplasmin for VMT (Fig. 6.34.4). This was reported to be effective in inducing completion of the persistent vitreomacular attachment and may hold promise as an alternative to surgical intervention.<sup>49</sup> The MIVI-TRUST (Microplasmin for Intravitreal Injection–Traction Release without Surgical Treatment) studies, two parallel prospective randomized series, have demonstrated that a release of the vitreomacular attachment is experienced in 26.5% of ocriplasmin-treated eyes compared with 10.1% of placebo-treated eyes (see Fig. 6.34.4). Eyes with focal adhesion of the vitreous (<1500 microns in diameter) and without coincident ERMs are better candidates for effective release.<sup>49,50</sup> Several follow-up, after approval,

and real-world studies have been presented, generally suggesting that the actual success rates can be optimized by targeting the ideal patient population.<sup>51</sup>

Of concern, however, is that, as in vitrectomy, postoperative macular hole formation is not rare. Thus, although this option avoids surgical intervention, albeit with a lower anatomical success rate, it is not clear that it does so with a lower rate of trauma to the inner foveal layer.<sup>49</sup> Moreover, there have been several reports of transient and persistent visual obscurations, either from the mechanical extrication or hypothetically from side effects of the lysis action on other tissues, such as the extracellular matrix.<sup>52,53</sup> Although eyes suffering toxicity with ocriplasmin cannot be predicted, are relatively rare, and are frequently transient, they may be quite distressing to individual patients. Persistent or even appearance of subfoveal fluid has been described after release of VMT, whether surgically or pharmacologically induced; although self-limiting, this may persist for several months.<sup>54</sup>

What is clear from the preclinical studies is that the recommended dosage should *never* be increased, and a second dose should *never* be administered, as there is a high rate of zonular dehiscence (and possibly other consequences parallel to the same biochemical action).<sup>55</sup> Although pharmacological therapy intuitively seems less invasive and less expensive, the complication rate is not trivial and is still being defined. Rudimentary calculations, furthermore, suggest that it is not as cost effective as vitrectomy, yet is cost effective compared with other medical interventions.<sup>56</sup> The better prognosis for eyes without ERMs and with smaller attachment sites may optimize the application and role of ocriplasmin.

## Pneumatic Vitreolysis

The newest therapeutic strategy is pneumatic vitreolysis. This approach was initially introduced >20 years ago for early macular holes before OCT was available to aid in diagnosis,<sup>57</sup> and there has been a resurgence of interest as a result of its potential to be effective without surgery or pharmacological side effects. Preliminary studies have reported results of 80% lysis of VMA, with subsequent improvements in visual acuity.<sup>58,59</sup> Although pneumatic vitreolysis also offers the benefit of avoiding surgical intervention, its complication rate, such as induced macular holes, are incompletely defined; in addition, because new retinal tears occur in many eyes undergoing pneumatic retinopexy for retinal detachment repair, the same might prove true in this application (see Fig. 6.34.4).

## CONCLUSIONS

OCT offers unprecedented imaging of vitreomacular traction, effectively defining what we now call VMT syndrome. Although there have been many studies of various treatment modalities, the optimal treatment options at this point have not been fully defined, and only deduced recommendations exist from these as well as a meta-analysis.<sup>60,61</sup> Hence it is left to the clinician's judgment to individualize treatment decisions.

# Cystoid Macular Edema

Matthew T. Witmer, Peter Coombs, Szilárd Kiss

# 6.35

**Definition:** Pathological swelling of the layers of the macular neurosensory retina with the formation of cystic spaces.

## Key Features

- Intraretinal fluid accumulation into “cyst-like” pockets within the retina.
- Increase in thickness of the central macula.
- Loss of foveal depression.
- Classic fluorescein angiography appearance consists of leakage of dye in a “petalloid” configuration surrounding the fovea.

## Associated Features

- Optical coherence tomography the most sensitive method of detection.
- Evidence of ocular (anterior chamber or vitreous) inflammation.
- Optic nerve head edema.
- Subretinal fluid.
- Loss of foveal reflex.
- Decreased visual acuity.
- Other evidence of retinal vascular incompetence, such as intraretinal hemorrhages and micro- or macroaneurysms.

## INTRODUCTION

Cystoid macular edema (CME) is swelling of the layers of the neurosensory retina within the macula. When excess fluid builds in the retina, it typically collects in “pockets,” referred to as “cysts” (Fig. 6.35.1). Classically, CME has been defined as being located extracellularly, within the outer plexiform layer of the retina. However, neither the exact cellular location (intracellular versus extracellular) nor the precise retinal layer of fluid accumulation is definitively known. In fact, improved imaging techniques suggest that the fluid may be located simultaneously within multiple layers of the retina.<sup>1</sup> CME is a subtype of macular edema with specific clinical, angiographic, and optical coherence tomography (OCT) characteristics.

CME may have severe implications for the function of the retina, including decreased visual acuity and contrast sensitivity. Acute or chronic edema causes anatomical disruption that may result in cellular dysfunction and death. Treatment of CME is important because chronic edema may result in degenerative changes in the macula and permanent loss of vision.<sup>2-6</sup> In addition, large cystic changes in the retina may lead to thinning and loss of inner retinal tissue or to formation of lamellar holes.<sup>7,8</sup>

## PATHOGENESIS AND ETIOLOGY

Physiologically, intraretinal fluid may accumulate into CME by one of three possible mechanisms.<sup>3</sup> The first two mechanisms consist of a breakdown of normal anatomical barriers: inner and outer blood–retinal barriers. The inner blood–retinal barrier consists of tight junctions between

**Fig. 6.35.1** Optical coherence tomography (OCT) image of a patient with cystoid macular edema (CME) from a central retinal vein occlusion (CRVO). The image demonstrates large intraretinal cystic spaces and subretinal fluid.

the endothelial cells of the retinal blood vessels as they traverse the inner retina. Several inflammatory mediators, such as prostaglandins, leukotrienes, protein kinase C, nitric oxide, vascular endothelial growth factor (VEGF), and various other cytokines, may cause incompetence of this barrier. The outer blood–retinal barrier is formed between adjacent retinal pigment epithelium (RPE) cells and is maintained by tight junctions, known as the *zonulae occludens*. The failure of the integrity of either of these barriers may allow fluid to accumulate in the retina.

The third mechanism results from the failure of a normal physiological process. In a normal functioning retina, the RPE cells constantly act to eliminate fluid from the retina. If this function is compromised, fluid may accumulate in the retina.

The etiologies of CME are numerous and heterogeneous but can be grouped according to the most likely pathological mechanism of retinal dysfunction (Box 6.35.1).

## Vascular

Macular edema, in particular CME, is the leading cause of vision loss in patients with diabetes mellitus. Long-term hyperglycemia produces retinal vascular damage mediated by several inflammatory factors, including VEGF. Histologically, edema is typically associated with basement membrane thickening, pericyte loss, endothelial cell death, and retinal vessel capillary closure. The severity of CME is typically correlated with the extent of diabetic retinopathy. Intensive glycemic control decreases the risk of the development of retinopathy and slows the progression of existing retinopathy.<sup>9</sup>

Central retinal vein occlusion (CRVO) and branch retinal vein occlusion (BRVO) are also common causes of CME (see Fig. 6.35.1). It is theorized that once venous occlusion occurs, pressure in the capillaries of the retinal vessels increases, with subsequent leakage of fluid into the retina as a result of the elevated capillary pressure.

Retinal macroaneurysms are a dilation of a retinal vessel wall in an area of vessel weakness. This condition may cause a breakdown of the inner blood–retinal barrier and may also allow intravascular fluid to accumulate within the outer neurosensory retina.<sup>10</sup>

Damage to retinal blood vessels may also account for the development of retinopathy from radiation exposure. The fundoscopic evidence of damage is typically delayed in onset from the time of radiation exposure. Clinically and histologically, the retinopathy resembles the vasculopathic changes seen in diabetic retinopathy. Microaneurysms, cotton-wool spots, retinal hemorrhages, and optic nerve edema may also occur.

Juxtafoveal retinal telangiectasis (JRT) leads to intraretinal exudation through retinal capillary vessel incompetence (Fig. 6.35.2). Clinically, this condition may be identified by the appearance of telangiectasias in the temporal macula but, histologically, resembles diabetic retinopathy. Gass and Blodi classified the condition into three groups, based on laterality and clinical appearance.<sup>11</sup> Type I appears to be a retinal vascular disorder akin to focal Coats' disease. Type II, however, may be a neurodegenerative disorder affecting Müller cells. Type II JRT manifests with loss of retinal tissue that can appear cystic on OCT. There will be leakage on fluorescein angiography (FA) but no true CME.

Coats' disease is a retinal vascular disorder that presents with retinal telangiectasia, ectatic arterioles, microaneurysms, and vessel exudation accompanied by retinal detachment. The edema may extend from the periphery into the macula.

CME has also been identified in neonates with retinopathy of prematurity (ROP).<sup>12–14</sup> In the majority of these patients, it is not identifiable with indirect ophthalmoscopy but requires OCT imaging. CME has been reported to be present in 50% of neonates at risk for ROP (median age 26 weeks), with the cystoid spaces most commonly found in the inner nuclear layer, and almost always bilaterally.<sup>13</sup> The presence and severity of the CME has been associated with plus disease, higher ROP stage, and subsequent need for laser treatment.<sup>13</sup>

Choroidal neovascularization (CNV) may lead to severe vision loss through photoreceptor damage, chorioretinal scarring, and CME (Box 6.35.2). CNV is an “ingrowth” of new vessels from the choriocapillaris into the retina, through a break in Bruch's membrane. In the older population, the most common cause of CNV is age-related macular degeneration (AMD; see Chapter 6.29).

Acutely elevated blood pressure may lead to a serous retinal detachment and CME. It has been speculated that the increase in blood pressure may damage blood vessel walls and cause ischemic damage to the RPE.<sup>15</sup> Damage to the RPE can potentially cause a breakdown of the outer blood–retinal barrier.

## BOX 6.35.1 Ocular Diagnoses Associated With Cystoid Macular Edema

### Vascular

- Retinal vascular
  - Diabetic retinopathy
  - Retinal vein occlusion—branch or central
  - Retinal artery macroaneurysm
  - Radiation retinopathy
  - Juxtafoveal retinal telangiectasis
  - Coats' disease
  - Retinopathy of prematurity
  - Ocular ischemic syndrome
- Choroidal vascular
  - Choroidal neovascularization (CNV) (see Box 6.35.2)
  - Hypertensive retinopathy

### Postoperative

- Irvine–Gass syndrome
- Penetrating keratoplasty
- Scleral buckle
- Laser treatment (Argon or yttrium–aluminum–garnet [YAG])
- Cryotherapy
- Panretinal photocoagulation

### Inflammatory

- Uveitis
- Human leukocyte antigen (HLA)-B27
- Birdshot chorioretinopathy
- Behçet's disease
- Eales' disease
- Vogt–Koyanagi–Harada disease
- Sarcoidosis
- Scleritis
- Pars planitis
- Immune recovery uveitis
- Infectious uveitis (cytomegalovirus, toxoplasmosis, herpesvirus)
- Neuroretinitis
- Multiple infectious causes (i.e., *Bartonella*, Lyme, syphilis, viral)
- Idiopathic retinal vasculitis, aneurysms, neuroretinitis (IRVAN)

### Medication Use

(See Box 6.35.3.)

### Retinal Dystrophies

- Retinitis pigmentosa
- Autosomal dominant cystoid macular edema
- Gyrate atrophy
- Goldman–Favre (enhanced S-cone) syndrome
- Juvenile X-linked retinoschisis

### Tractional

- Epiretinal membrane
- Vitreomacular traction syndrome
- Vitreoretinal traction associated with myopia
- Macular hole

### Anatomical

- Optic nerve
  - Optic pit maculopathy
  - Optic disc coloboma
  - Morning glory disc anomaly
- Retina
  - Retinal detachment

### Neoplastic

- Tumors
  - Retinal—hemangiomas
  - Choroidal—melanoma, hemangioma, osteoma

## Postoperative

CME is a frequent complication following cataract surgery and is also known as Irvine–Gass syndrome.<sup>16</sup> Angiographic CME may be detected in as many as 20% of uncomplicated surgeries but is only visually significant in 1%–2%.<sup>17</sup> This makes CME the most common cause of vision loss after

**Fig. 6.35.2** Optical coherence tomography (OCT) image of a patient with apparent cystoid macular edema (CME) from juxtafoveal retinal telangiectasis (JRT) type 2. Note the normal foveal contour. The CME is typically located near the foveola. Although cysts appear on OCT in this condition, loss of retinal tissue may be the underlying cause as opposed to excess fluid.

### BOX 6.35.2 Causes of Choroidal Neovascularization

#### Degenerative Diseases

- Age-related macular degeneration
- Myopic degeneration
- Angioid streaks
- Juxtafoveal retinal telangiectasis
- Vitelliform macular dystrophy
- Pattern dystrophies
- Stargardt macular dystrophy

#### Inflammatory

- Vogt–Koyanagi–Harada syndrome
- Behçet's syndrome
- Sympathetic ophthalmia
- Multifocal choroiditis
- Serpiginous
- Laser photocoagulation
- Punctate inner choroiditis

#### Infectious

- Toxocariasis
- Toxoplasmosis
- Ocular histoplasmosis

#### Trauma

- Choroidal rupture

#### Choroidal Masses

- Choroidal osteoma
- Choroidal melanoma
- Choroidal hemangioma

#### Idiopathic

as prostaglandins, leukotrienes, and histamine, which may make retinal vessels more permeable.

CME may also occur as a complication of intraocular laser therapy. This includes panretinal photocoagulation (PRP) and neodymium:yttrium–aluminum–garnet (Nd:YAG) laser. Possible pathological mechanisms of this phenomenon include the release of inflammatory mediators or the increase of macular blood flow leading to transudation.<sup>3</sup> This provides the rationale for treating pre-existing CME prior to initiating PRP. The incidence of CME after YAG is quite low (<3%), although it may be increased if the laser is performed early in the postoperative period.<sup>23,24</sup>

Cryotherapy, which is typically used in the treatment of retinal tears or detachment, may also cause CME.<sup>25,26</sup>

Several surgical procedures other than cataract surgery are also suspected to cause CME. These include penetrating keratoplasty, vitrectomy, and scleral buckling. The incidence of CME after a scleral buckling procedure is low (<5%).<sup>27</sup>

### Uveitis-Related

CME is the most common cause of decreased vision in patients with ocular inflammatory disease.<sup>28,29</sup> The causes of uveitis are varied and can be classified according to the suspected etiology or location of inflammation. Although CME is most commonly associated with posterior uveitis, it may also be associated with intermediate or anterior uveitis. The pathological mechanism of CME in uveitis likely relates to the compromise of the inner blood–retinal barrier as a result of exposure to intraocular inflammatory mediators, such as prostaglandins, leukotrienes, tumor necrosis factor- $\alpha$ , and VEGF,<sup>30</sup> among others.

Intraocular inflammation that affects the optic nerve and macular retina is called *neuroretinitis*. There are infectious (i.e., *Bartonella henselae*, *Toxoplasmosis*, *Toxocariasis*, *Syphilis*, etc.) and noninfectious etiologies of this condition (i.e., sarcoidosis, etc.), which also displays CME<sup>31</sup> (see Part 7: Uveitis and Other Intraocular Inflammations).

### Medication-Related

Several medications have been linked to the development of CME (Box 6.35.3).<sup>32–46</sup> The most commonly used topical medications that have been linked to CME are the prostaglandin analogues.<sup>43</sup> It is thought that prostaglandins might lead to the vascular incompetence of retinal vessels through their proinflammatory effects within the eye. Fingolimod,

cataract surgery. Certain preoperative and operative characteristics may increase the incidence of postoperative CME, such as diabetes,<sup>18</sup> uveitis,<sup>19</sup> intracapsular versus extracapsular surgery,<sup>20,21</sup> and intraoperative vitreous loss.<sup>22</sup>

The pathological mechanism for Irvine–Gass syndrome is unknown, although it may be related to the production of intraocular inflammation. The surgery causes the release of inflammatory mediators, such

**Fig. 6.35.3** Optical coherence tomography (OCT) image of a patient with juvenile X-linked retinoschisis. There are several schisis cavities noted throughout the macula.

#### BOX 6.35.3 Medications Causing Macular Edema

- Benazalkonium chloride<sup>32</sup>
- Carmustine (BCNU)<sup>33,34</sup>
- Docetaxel<sup>35</sup>
- Epinephrine<sup>36,37</sup>
- Fingolimod<sup>38</sup>
- Glitazones<sup>39</sup>
- Ipilimumab<sup>40</sup>
- MEK inhibitors<sup>41</sup>
- Niacin<sup>42</sup>
- Paclitaxel<sup>43</sup>
- Prostaglandin analogues<sup>44</sup>
- Tamoxifen<sup>45</sup>
- Timolol<sup>32,46</sup>

which is used to treat multiple sclerosis, can cause CME in 0.2%–1% of patients by altering S1P receptor signaling and altering endothelial integrity. It typically presents in the first 3–4 months of therapy.<sup>47,48</sup> Newer chemotherapy agents have been implicated. MEK inhibitors are associated with CME.<sup>41</sup> Cytotoxic T lymphocyte antigen 4 (CTLA4) antagonists, such as ipilimumab, are rarely associated with uveitis and concomitant CME.<sup>40</sup> Paclitaxel, used to treat breast cancer and other cancers, is associated with CME, does not leak on FA, and may be related to Müller cell dysfunction.<sup>49</sup>

### Retinal Dystrophies

Several macular dystrophies are also associated with the development of CME. Among these are retinitis pigmentosa (RP),<sup>50</sup> dominantly inherited macular edema,<sup>51</sup> Goldman–Favre syndrome (Fig. 6.35.3), gyrate atrophy, and juvenile X-linked retinoschisis.

Although the precise mechanism for CME in RP is unknown, it is hypothesized that the accumulation of fluid is the result of the failure of the RPE pump to function properly.<sup>52,53</sup> CME in RP may remain subclinical for many years with retention of good visual acuity. There appears to be an association between the presence of antiretinal antibodies and the presence of CME in RP<sup>54</sup> (see Chapter 6.14).

### Tractional Causes

The tractional causes of CME include epiretinal membrane (ERM), vitreomacular traction (VMT) syndrome, myopic traction maculopathy (myopic macular schisis), and macular holes.

ERMs are proliferations of cells that form an avascular fibrous membrane along the surface of the inner retina. They are often associated with CME that is unresponsive to topical medication (Fig. 6.35.4).

VMT syndrome is a condition in which the vitreous becomes detached anteriorly but remains attached at the macula. The tractional forces of the attached vitreous are associated with CME. In a retrospective study of 53 symptomatic eyes with this syndrome, 81% were found to have cystoid macular changes.<sup>55</sup> A variant of this syndrome, termed *tractional CME*, also has been described.<sup>56</sup>

Similar to the traction in VMT, severe traction with macular edema and a retinoschisis-like appearance can also develop in highly myopic patients with posterior staphylomas (see Chapter 6.34).

### Anatomical

Patients with optic nerve head anomalies may also develop intraretinal fluid that appears cystoid. These lesions include optic nerve colobomas, optic nerve pits, and morning glory disc anomaly.

Optic nerve pits are congenital anomalies that may allow for fluid to infiltrate the retina.<sup>57</sup> The origin of the intraretinal fluid is controversial, but the most likely sources are the vitreous cavity and the subarachnoid space. A recent study using high-resolution OCT revealed that fluid was found in the outer nuclear layer of the retina in 94% of eyes with optic pit maculopathy and in the inner nuclear layer of the retina in 81%<sup>1</sup> (see Chapter 6.36).

Retinal detachments of various etiologies may also demonstrate CME. The exact origin of the fluid is not known; however, damage to both the inner and outer blood–retinal barriers and the RPE pump mechanism have been implicated.

### Intraocular Neoplasms

Several intraocular tumors, including choroidal melanomas, choroidal hemangiomas, and vasoproliferative tumors, may also present with CME.<sup>58,59</sup> The presence of CME associated with choroidal melanomas can often be directly related to a mass located underneath the fovea and is often associated with subfoveal exudate.<sup>59</sup> The molecular basis for CME

**Fig. 6.35.4** Optical coherence tomography (OCT) image of a patient with large cystic cavities as the result of traction from an epiretinal membrane.

associated with an intraocular tumor is unclear; however, it may be related to disruption of the RPE pump and/or barrier function resulting from compression from the choroidal mass.

## DIAGNOSIS AND ANCILLARY TESTING

### Fundoscopy

Clinical examination reveals intraretinal cystic structures extending radially from the foveola. The cysts often form a tear-drop configuration as they taper to a point toward the center of the fovea.<sup>60</sup> Additional fundoscopic signs include evidence of intraocular inflammation, optic nerve edema, subretinal fluid, retinal thickening, and loss of the foveal reflex.

### Optical Coherence Tomography

OCT is a very sensitive modality for visualization of CME.<sup>61</sup> The resolution of this diagnostic instrument now approaches the level of histological examination, at less than 10  $\mu\text{m}$ . Several studies have investigated the ability of spectral-domain OCT (SD-OCT) to image CME from a variety of causes and compare it with conventional retinal imaging modalities, such as FA<sup>62,63</sup> (see Chapter 6.7).

### Autofluorescence

Autofluorescence can also be used to detect CME. Imaging will reveal subtle areas of hyperfluorescence in the areas containing cysts. This is thought to result from the thinning of macular pigments in the fovea from the CME, which would typically block the background choroidal hyperfluorescence.<sup>60</sup>

### Fluorescein Angiography

FA of eyes with CME typically demonstrates a gradual increase in hyperfluorescence throughout the diagnostic study. The initial hyperfluorescence occurs as a result of thinning of the macular pigment in the fovea and loss of blocking of the choroidal hyperfluorescence, whereas gradual increase in hyperfluorescence occurs as the cysts fill with fluid that leaks from the perifoveal capillaries. Because of the anatomical arrangement of the outer plexiform layer, the hyperfluorescence often demonstrates a “petaloid” appearance (Fig. 6.35.5).

**Fig. 6.35.5** Fluorescein angiogram from a patient with classic “petaloid” appearance of fluorescein leakage in the late phase of the angiogram.

Several causes of macular edema, however, do not hyperfluoresce or “leak” during FA (Box 6.35.4). This difference in FA behavior among entities may provide important diagnostic information for the clinician (see Chapter 6.6).

## TREATMENT

The treatment of CME is dependent on etiology.

**BOX 6.35.4 Etiologies of Cystoid Macular Edema Without Leakage on Fluorescein Angiography**

- Epinephrine
- Epiretinal membrane retinoschisis
- Goldman–Favre syndrome (enhanced S-cone) syndrome
- Juvenile X-linked retinoschisis
- Myopic retinoschisis
- Niacin
- Retinitis pigmentosa
- Taxanes—docetaxel or paclitaxel
- Vitreomacular traction syndrome

**Vascular****Diabetic Macular Edema (See Chapter 6.22, Diabetic Retinopathy)**

In 1985, the “gold standard” for the treatment of diabetic macular edema was established as focal laser photocoagulation.<sup>64</sup> The treatment of “clinically significant macular edema” reduces the risk of vision loss and increases the chance of visual improvement.

More recently, prospective studies suggest that either monotherapy with an anti-VEGF antibody (ranibizumab) or combined ranibizumab plus deferred focal laser photocoagulation resulted in the best visual outcome with the least complications in a period of 2 years compared with laser alone or intravitreal corticosteroids alone.<sup>65</sup>

**Retinal Venous Occlusive Disease (See Chapter 6.20, Venous Occlusive Disease of the Retina)**

Treatment options for CME associated with retinal venous occlusive disease have historically evaluated BRVO and CRVO independently.

**Branch Retinal Vein Occlusion**

For over 2 decades, vision loss caused by CME resulting from BRVO had been treated with laser photocoagulation.<sup>66</sup> Intravitreal triamcinolone has also been shown to be as effective as laser to treat CME resulting from BRVO, but with more adverse effects.<sup>6</sup> Recently, monotherapy with anti-VEGF agents have emerged as the first-line therapy for CME secondary to BRVO.<sup>67</sup>

**Central Retinal Vein Occlusion**

Until the past decade, the treatment of CME from CRVO consisted of observation.<sup>68</sup> Subsequently, prospective trials demonstrated that both intravitreal anti-VEGF agents<sup>69</sup> and corticosteroids<sup>5</sup> were effective in treating CME secondary to CRVO. Because of their superior efficacy and safety, anti-VEGF agents are now the treatment of choice.<sup>5</sup>

**Macroaneurysms (See Chapter 6.28, Retinal Arterial Macroaneurysms)**

The macular edema associated with macroaneurysms has been treated with laser photocoagulation applied to the surface of the leaking vessel with large spot sizes and light burns with little evidence that it is effective.<sup>70</sup> More recently, anti-VEGF therapy has been used to treat macular edema from this condition and has demonstrated efficacy in small case reports.<sup>71</sup>

**Juxtafoveal Retinal Telangiectasias (See Chapter 6.25, Coats’ Disease and Retinal Telangiectasia)**

CME from group 1 JRT may be treated with laser photocoagulation to the leaking vascular anomalies. In eyes with group 2 JRT, however, treatment with laser photocoagulation not only has shown limited success in terms of increasing visual acuity but also can stimulate secondary CNV formation.<sup>72</sup> The use of intravitreal anti-VEGF medication is able to decrease retinal thickness, but not improve visual acuity.<sup>73</sup> In fact, recommendations from a prospective trial have recommended against the use of monthly ranibizumab to treat macular edema from group 2.<sup>74</sup> The use of anti-VEGF medication to treat edema related to choroidal neovascularization in JRT<sup>75,76</sup> or edema associated with a foveal detachment,<sup>77</sup> however, has demonstrated benefit in small case series.

**Coats’ Disease (See Chapter 6.25, Coats’ Disease and Retinal Telangiectasia)**

The treatment of Coats’ disease centers on the application of laser photocoagulation or cryotherapy to leaking retinal capillaries.

**Radiation Retinopathy (See Chapter 6.26, Radiation Retinopathy and Papillopathy)**

CME associated with radiation retinopathy may be treated with laser photocoagulation to close incompetent vessels; however, intravitreal triamcinolone has also demonstrated the ability to stabilize or improve visual acuity in these eyes.<sup>78</sup> In a small case series, ranibizumab was also found to improve visual acuity in patients with radiation maculopathy.<sup>79</sup>

**Age-Related Macular Degeneration (See Chapter 6.29, Age-Related Macular Degeneration)**

Because CME related to exudative AMD is caused by underlying CNV, the treatment of the CME consists of treatment of the CNV. The treatment of CME related to AMD has evolved rapidly in recent years. Anti-VEGF agents are now the treatment of choice and have a beneficial effect on intraretinal fluid from CNV.<sup>80-84</sup>

**Postoperative**

Treatment of pseudo-phakic CME consists of several options. In many instances, however, no treatment is necessary because the natural history of the disease often results in resolution of the edema.<sup>85,86</sup> Despite the vast amount of treatment options, no prospective, placebo-controlled, double-masked, randomized controlled trial has been performed to evaluate the treatment options for acute pseudo-phakic CME.<sup>87</sup>

Medical treatment options include nonsteroidal anti-inflammatory drugs (NSAIDs). These can be delivered topically, locally, or systemically. Topical NSAIDs are effective for both prophylaxis and treatment of pseudo-phakic CME.<sup>88</sup> Topical ketorolac 0.5%, specifically, has been shown to increase the visual acuity in patients with chronic CME after cataract surgery.<sup>89</sup> The use of NSAIDs prophylactically in high-risk patients has also increased in recent years. Despite the fact that several new NSAIDs have been developed, none of these medications have been shown in humans to have a distinct advantage in outcomes over the use of ketorolac.<sup>90</sup>

The use of corticosteroids has been shown to have significant benefits in the treatment of pseudo-phakic CME. These may be delivered topically, periocularly, intravitreally, or systemically. The use of a topical corticosteroid (prednisolone acetate 1%), combined with the use of topical ketorolac 0.5%, has been shown to be more likely to lead to an increase in visual acuity compared with treatment with either agent alone.<sup>91</sup> Topical difluprednate, a more potent topical corticosteroid, may also be used to treat pseudo-phakic CME.<sup>92</sup>

Additional medications that may be beneficial in pseudo-phakic CME include carbonic anhydrase inhibitors and anti-VEGF agents. A retrospective study suggested that intravitreal bevacizumab may be beneficial for the treatment of refractory pseudo-phakic CME.<sup>93</sup> This, however, requires further study in a prospective, randomized manner.

Surgical treatment for pseudo-phakic CME may be indicated if vitreous traction on the retina or iris is stimulating intraocular inflammation. Pars plana vitrectomy in eyes with chronic pseudo-phakic CME and vitreous adhesions in the anterior segment after cataract surgery may improve visual acuity.<sup>94,95</sup> Alternatively, laser (typically, Nd:YAG) may be used to release the traction that may be causing inflammation and CME.

**Inflammatory (See Part 7: Uveitis and Other Intraocular Inflammations)**

The treatment of uveitis-related CME consists primarily of controlling the source of inflammation. When an infectious etiology has been ruled out, treatment often begins with the use of NSAIDs and corticosteroids. These may be delivered in a topical format, locally, intravitreally, or systemically. In a recent clinical trial of the treatment of chronic noninfectious posterior uveitis, a sustained delivery implant of fluocinolone acetonide demonstrated efficacy.<sup>96</sup>

In patients unable to tolerate corticosteroids for the treatment of uveitis or in those who need chronic immunosuppression to control intraocular

inflammation, systemic immunomodulatory medication may be necessary to control inflammation and decrease CME.<sup>97</sup>

## Medication Induced (See Chapter 6.45, Retinal Toxicity of Systemically Administered Drugs)

In patients with CME related to medication use, cessation of the medication, if possible, is advised. CME caused by fingolimod or CTLA4 antagonists may be responsive to ocular corticosteroids.<sup>40,41</sup> CME resulting from use of paclitaxel has been treated with topical dorzolamide 2%.<sup>49</sup>

## Retinal Dystrophy (See Chapter 6.14, Progressive and 'Stationary' Inherited Retinal Degenerations)

The treatment options for CME associated with RP are limited. Oral acetazolamide was found to be effective in improving visual acuity in a small set of patients with CME caused by RP.<sup>98</sup> Topical dorzolamide has also been shown to be effective in decreasing the amount of edema in many patients with RP and CME.<sup>99,100</sup> The use of oral acetazolamide, however, may be more effective than the topical use of dorzolamide in terms of improving the resolution of edema and improving visual acuity, however, the side effects of systemic medications are potentially more numerous and require close monitoring.<sup>88</sup> Injection with intravitreal corticosteroids, such as triamcinolone, has also been attempted for CME from RP, although the results were variable and not sustained.<sup>53</sup> Similarly, the use of bevacizumab has not demonstrated efficacy in RP-related CME.<sup>101</sup>

## Tractional (See Chapter 6.32, Macular Hole, Chapter 6.33, Epiretinal Membrane, Chapter 6.34, Vitreomacular Traction Syndrome)

The treatment of CME associated with a tractional etiology has focused on relief of the traction. For eyes with an ERM, surgical peeling typically allows for the edema to resolve.<sup>102</sup> Similarly, in eyes with macular holes, closure of the hole often resolves the edema.

Vitrectomy to remove the vitreous adhesion to the macula in VMT syndrome<sup>103,104</sup> and in myopic eyes with a retinoschisis-like appearance<sup>105</sup> is often effective. Recently, the use of intravitreal microplasmin to create a posterior vitreous detachment pharmacologically has been performed.<sup>106-108</sup> This treatment, however, requires further study.

## Anatomical Abnormalities (See Chapter 6.36, Coexistent Optic Nerve and Macular Abnormalities)

Previous treatments of optic disc maculopathy include pars plana vitrectomy, laser photocoagulation to the temporal margin of the optic disc, internal tamponade with gas, internal drainage of submacular fluid, or

insertion of a sponge explant.<sup>109</sup> Currently, however, there is no "gold standard" in terms of optimal treatment.

Retinal detachment repair often allows resolution of CME related to this condition.

## Neoplastic (See Part 8: Intraocular Tumors)

Treatment of intraocular tumors with radiation, cryotherapy, or laser photocoagulation often results in resolution of subretinal fluid and intraretinal edema.

## CONCLUSIONS

CME is a significant cause of vision loss. The treatments of this condition are as varied as its etiologies. The crucial step in the evaluation and management of this condition is determining the correct etiology. When a diagnosis is reached, an appropriate therapeutic option, with the least potential risk and greatest potential benefit can be administered.

# Coexistent Optic Nerve and Macular Abnormalities

## 6.36

Odette M. Houghton

**Definition:** A heterogeneous group of optic nerve disorders that have secondary pathological effects on the macular retina.

### Key Features

- Structural changes of the optic nerve.
- Secondary retinal detachment, schisis-like retinal degeneration, neovascularization, macular edema.

### Associated Features

- Optic nerve pit.
- Morning glory optic disc anomaly.
- Optic nerve coloboma.
- Choroidal neovascularization.
- Optic nerve abnormalities may be associated with macular abnormalities, the most common being retinal detachment.
- Choroidal neovascularization, macular edema, schisis-like degeneration, and lipid exudation may also be found.

## INTRODUCTION

The optic nerve head (optic disc) is the primary site of many congenital and acquired ocular disorders. The optic disc is the location where unmyelinated retinal derived axons become myelinated, and the central retinal artery and vein enter and exit the globe. This portion of the optic nerve borders the retina, retinal pigment epithelium (RPE), Bruch's membrane and choroid. Anomalies of this crucial juncture often lead to marked physiological consequences and macular abnormalities.

## CONGENITAL ANOMALIES OF THE OPTIC DISC

### Congenital Optic Disc Pit

Congenital optic disc pits are isolated excavations in the optic nerve head.<sup>1</sup> They are believed to be secondary to a disturbance in the development of the primitive epithelial papilla, but the exact cause is uncertain.<sup>2</sup> Occasionally, optic disc pits can be associated with other congenital disc anomalies, such as colobomas.

Optic disc pits are thought to occur in approximately 1 per 10000 patients,<sup>2</sup> without gender or racial predilection.<sup>1</sup> Pits present unilaterally in enlarged optic discs with a frequency of about 85%.<sup>2</sup> Rarely, more than one pit can be seen on a single optic disc.<sup>1</sup>

Optic disc pits appear as gray (60%), white/yellow (30%), or black (10%) and round or oval depressions in the optic nerve head.<sup>1</sup> The average size of an optic pit is  $\frac{1}{2}$  disc diameter.<sup>1</sup> Although over 50% of pits are located on the temporal aspect of the optic disc, they can be located in any sector. There is usually disturbance of the peripapillary retinal pigment epithelium (RPE) or choroidal atrophy associated with eccentrically located pits.

Histopathological studies and optical coherence tomography (OCT) of optic disc pits demonstrate herniation of dysplastic retina into a connective tissue-lined pocket that often extends into the subarachnoid space through a defect in the lamina cribrosa.<sup>3-5</sup> Condensed vitreous strands terminate at the margin of the pit (Fig. 6.36.1).<sup>2,6,7</sup>

Optic disc pit-associated maculopathy develops in 25%–75% of eyes and is more common with temporally located pits.<sup>1,2</sup> This maculopathy can

occur at any age but is most frequently observed in early adulthood.<sup>1,2</sup> The characteristic features of optic disc pit-associated maculopathy include retinoschisis-like degeneration of the nasal macula and shallow retinal detachments of the central macula (Fig. 6.36.2).<sup>7,8</sup> Spectral-domain OCT has advanced our understanding of the ultrastructural characteristics of optic disc pit-associated maculopathy. OCT analysis supports the theory that fluid originating from the pit can directly enter and extend into all layers of the retina, including the sub-internal limiting membrane (ILM) space, ganglion cell layer, inner nuclear layer, outer nuclear layer, and subretinal space (Fig. 6.36.3).<sup>9</sup> The fluid forms schisis-like cavities with intact vertical bridging elements in the retinal stroma. The retinal separation appears to be most prominent in the outer nuclear layers and may be combined with a striking elevation of the ILM.<sup>9,10</sup> The fluid may exit through a visible lamellar foveal hole or invisible breaks in the outer retina into the subretinal space.<sup>8,9</sup>

The precise pathogenesis of optic disc pit maculopathy is unclear. Various hypotheses regarding the conduit and source of fluid have been proposed. The most plausible origin of subretinal fluid associated with optic disc pits is the vitreous cavity<sup>1,2,7,10-12</sup> or the subarachnoid space.<sup>6,13</sup> The lack of extension of hyperfluorescence from the optic pit into the subretinal space on fluorescein angiography (FA) indicates that an increase in vascular permeability is not the source of fluid.<sup>2</sup>

Communication among the schisis cavities, subretinal space, and optic disc pit has been suggested to occur through either a visible or an invisible sieve-like fenestration in the membrane overlying the optic disc.<sup>11,12,14</sup> Evidence supporting communication between the vitreous cavity and subretinal space includes transport of India ink from the vitreous cavity into the pit and subretinal space in Collie dogs with cavitory disc anomalies (Fig. 6.36.4); subretinal migration of vitreous substitutes<sup>2,12</sup>; and intraoperative drainage of intraretinal and subretinal fluid through the disc anomaly.<sup>10,12</sup>

The herniated dysplastic retina, which extends into the subarachnoid space via the optic nerve pit, may be incompletely differentiated and porous.<sup>6</sup> The vitreous, subarachnoid space, and subretinal space may therefore be variably connected. Communication of fluid with the subarachnoid space is supported by OCT studies<sup>15</sup> and reports of intracranial migration of the silicone oil following vitrectomy.<sup>6,12,14</sup>

OCT has also demonstrated the presence of vitreomacular traction and vitreous strands over the optic disc, which may play an important role in the development of optic disc pit maculopathy.<sup>8,10,14,15</sup> The high postoperative recurrence rate and subretinal migration of vitreous substitutes argue against vitreous traction being the sole cause of fluid accumulation.<sup>12</sup> Johnson and Johnson proposed a mechanism whereby normal intermittent pressure fluctuations of the central spinal fluid are transmitted to the optic pit via the subarachnoid space.<sup>12</sup> In eyes with an impermeable optic pit capsule, the pit acts like a bulb syringe sucking in liquefied vitreous fluid during a drop in intracranial pressure. A later rise in intracranial pressure could force the vitreous fluid into the pit and into the retinal tissue or subretinal space. Traction may facilitate access to the intraretinal and subretinal space.<sup>10</sup>

Retinal detachments associated with optic disc pits may fluctuate and occasionally resolve without therapy. Because the visual prognosis in untreated cases is so poor, current recommendations include some form of aggressive treatment.

### Morning Glory Optic Disc Anomaly

The morning glory disc anomaly is a congenital malformation of the optic nerve. The precise pathogenesis of this disc anomaly is unknown. Theories

**Fig. 6.36.1** (A) Spectral-domain optical coherence tomography (SD-OCT) slice (*green arrow*) at the level of a temporally located congenital optic disc pit (B, *white arrow*), without associated maculopathy. Dense vitreous strands emerge from the optic disc pit and enter into vitreous cavity. (Courtesy Dr. Maurice B. Landers, III, Spectralis OCT, Heidelberg Engineering, Heidelberg, Germany.)

**Fig. 6.36.2** Temporally located congenital optic pit associated with a localized retinal detachment in the macula. Peripapillary retinal pigment epithelial changes are seen adjacent to the pit. Small yellow subretinal precipitates seen within the temporal aspect of the detachment. Precipitates appear as hyperreflective accretions adherent to the outer retina on optical coherence tomography (*not illustrated*) and punctate areas of intense autofluorescence on fundus autofluorescence imaging (*not illustrated in this figure*).

include faulty closure of the fetal fissure (i.e., a variant of optic nerve coloboma); a primary mesenchymal abnormality; a primary neuroectodermal dysgenesis; and dilation of the optic nerve head due to dysgenesis of the terminal optic stalk.<sup>16</sup> No definite genetic defect has been associated with this anomaly.

Morning glory disc anomaly is usually unilateral. It is characterized by a conical excavation of the posterior fundus that includes the optic nerve, a central tuft of glial tissue, peripapillary subretinal fibrosis, and straightened vessels emerging from the peripheral nerve in a radial pattern.<sup>17</sup> Macular involvement can occur in up to 50% of patients (Fig. 6.36.5).<sup>17</sup>

Contractility of the morning glory disc anomaly, with transient monocular vision loss corresponding to the contractions, has been reported.<sup>16</sup> Studies have correlated this phenomenon to the presence of intrascleral smooth muscle within the distal optic nerve.<sup>18</sup>

It is critical to distinguish this anomaly from optic nerve coloboma because these two entities have different systemic associations. Morning glory disc anomaly tends not to occur as part of a multisystem disorder. It can, however, be associated with basal encephalocele, hypopituitarism, and other central nervous system and cerebrovascular abnormalities.<sup>17</sup>

Patients with morning glory disc anomaly often present as infants with strabismus or leukocoria. Vision is typically poor and ranges from 20/200 to finger counting. However, cases with 20/20 vision and no light perception have been reported.<sup>16</sup> Decreased retinal function appears to be proportional to the extent of peripapillary retinal involvement.

Approximately one third of reported cases of this anomaly have been associated with nonrhegmatogenous retinal detachment. Retinal detachment typically occurs during the first or second decade of life. The retinal detachments may be large but are usually confined to the peripapillary retina or posterior pole.

As with optic disc pits, the pathogenesis and origin of subretinal fluid in morning glory disc anomaly remains undetermined. Evidence supporting communication between the subarachnoid space and subretinal space in morning glory disc anomaly includes the migration of metrizamide from cerebrospinal fluid into the subretinal space; and migration of gas from the vitreous cavity into the perineural subarachnoid space at the time of optic nerve sheath fenestration.<sup>18,19</sup> Peripapillary retinal breaks, identified intraoperatively, with OCT or biomicroscopy, together with reports of vitreous substitutes migrating into the subretinal space, suggest a vitreal origin.<sup>19,20</sup> It has been postulated that the glial tuft in morning glory disc anomaly can contract creating breaks or inducing abnormal communication between the subretinal and subarachnoid spaces.<sup>19,20</sup>

## Optic Nerve Coloboma

Colobomas can arise anywhere along the line of fusion of the embryonic fissure, which extends from the optic disc posteriorly to the inferior pupillary frill of the iris anteriorly. Inadequate closure of the superior end produces an optic nerve coloboma, whereas more widespread failure to close causes a retinochoroidal coloboma.

Optic nerve colobomas may be unilateral or bilateral. They appear as a white excavation, which typically involves the inferior part of the nerve and can extend inferiorly into the choroid and retina. The superior rim of the optic nerve is usually spared (Fig. 6.36.6).<sup>16</sup> There are often areas of pigment clumping at the junction of normal fundus and the colobomatous defect (Fig. 6.36.7). As with morning glory disc anomaly, there is contractility of some colobomatous optic discs, which is thought to be due to the presence of heterotopic intrascleral smooth muscle.<sup>16</sup>

**Fig. 6.36.3** Optical coherence tomography (OCT\*) slice at the level of the optic nerve pit (left). Multilayered schisis-like separation of the nasal inner retina and intact vertical bridging elements in the central outer nuclear layer, without retinal detachment (left and right). (Courtesy Dr. Maurice B. Landers III \* Spectralis OCT, Heidelberg Engineering, Heidelberg, Germany.)

**Fig. 6.36.4** Histopathology of a Collie dog's eye with a congenital optic pit and associated serous retinal detachment. Vitreous gel has entered the pit from the vitreous cavity, and a connection exists between the pit and the subretinal space (periodic acid–Schiff.)

Both retinochoroidal and optic nerve colobomas may be associated with systemic abnormalities arising from midline defects. One syndrome found in conjunction with retinochoroidal colobomas is CHARGE (coloboma, heart disease, atresia choanae, retarded growth, genital hypoplasia, ear anomalies, with or without deafness) syndrome.

Papillorenal syndrome is an autosomal dominant condition in which renal and urinary tract malformations are associated with optic nerve coloboma, retinochoroidal coloboma, congenital optic pit, and morning glory disc anomaly. A mutation of the *PAX2* gene has been noted in 50% of such patients.<sup>21</sup> Papillorenal syndrome has also been associated with serous retinal detachment,<sup>22</sup> foveal hypoplasia, and pigmented macular atrophy (see Fig. 6.36.7).<sup>21</sup>

**Fig. 6.36.5** Morning glory optic disc in this left eye is associated with a shallow retinal detachment. The yellow pigment that overlies the area of subretinal fibrosis at the 3 o'clock position is caused by the xanthophyll pigment in the fovea, which is abnormally close to the disc.

**Fig. 6.36.6** Congenital optic nerve coloboma involving the inferior part of the nerve and sparing the superior rim of the optic nerve. (Courtesy Sarah Armstrong CRA, C-OCT.)

**Fig. 6.36.7** Montage fundus photograph showing a retinochoroidal coloboma involving the optic nerve in a patient with CHARGE (coloboma, heart disease, atresia choanae, retarded growth, genital hypoplasia, ear anomalies, with or without deafness) syndrome. A deep ectatic area is noted inferior nasal to the identifiable optic disc. Blood vessels emerge at the inferior border of this area. Superficial blood vessels are visualized coursing over the colobomatous defect. Deep choroidal blood vessels are seen in the base of the inferior defect. There is pigment disturbance at the junction of the normal fundus and colobomatous defect. The surrounding normal retina is attached. (Courtesy Dr. Travis A. Meredith.)

Among the ocular abnormalities associated with both optic nerve and retinochoroidal coloboma are rhegmatogenous, serous, or traction retinal detachments.

## Treatment of Retinal Detachments Secondary to Congenital Anomalies of the Optic Disc

Retinal detachments associated with congenital anomalies of the optic disc have many similarities.

If subretinal fluid seen in conjunction with an optic disc anomaly is minimal and borders only a portion of the optic disc, peripapillary photocoagulation alone can be considered. The most widely used technique is the placement of 2–5 rows of 200 micron spot-size burns along the disc margin, extending into flat retina on either side of the subretinal fluid (Fig. 6.36.8).<sup>23,24</sup> If the photocoagulation is ineffective, it can be repeated 2 months later. The greater the separation of the peripapillary retina from the underlying RPE, the less likely it is that the treatment will be successful.

More extensive retinal detachments will require vitrectomy, with separation of the posterior hyaloid and careful dissection of all peripapillary fibroglial tissue. If a retinal break is present, it is important to relieve the surrounding traction. A fluid–gas exchange should be performed, draining the subretinal fluid over the optic disc or, in the case of retinochoroidal colobomas, a break in the dysplastic retina overlying the colobomatous defect. Endophotocoagulation should be applied to the margin of the defect.<sup>19</sup> In the case of retinochoroidal colobomas, if the retinal break is located peripherally, scleral buckling surgery may be effective.

Successful displacement of the subretinal fluid with an intravitreal gas injection alone has been reported in detachments associated with optic disc pits. However, the beneficial effects of this technique may only be temporary secondary to recurrence of fluid movement into the subretinal space from persistent inner layer cavities.<sup>14</sup> Vitrectomy, either with or without ILM peel in eyes with optic disc pit maculopathy, has yielded promising results.<sup>23,25</sup> A combination of carefully titrated preoperative juxtapapillary laser photocoagulation with immediate vitrectomy and gas tamponade has been reported to be effective in a series of 11 patients.<sup>26</sup> Conversely, Hirakata et al. reported a high success rate in the treatment of detachments secondary to optic disc pits with induction of posterior vitreous detachment during vitrectomy, without gas tamponade or

**Fig. 6.36.8** Two rows of 200  $\mu$ m spot-size laser burns applied to the peripapillary fundus in an eye with a congenital optic pit and macular retinal detachment. The treatment is carried into flat retina superiorly and to the area of detachment inferiorly, so the retinal pigment epithelium can adhere to the retina and, hopefully, to continue that adherence centrally.

**Fig. 6.36.9** Pigmented peripapillary choroidal neovascular membrane developing in an eye with optic nerve head drusen.

photocoagulation.<sup>10</sup> Promising results have been demonstrated with placement of tissue adhesive, autologous sclera, fibrin, or platelet concentrate over the optic pit.<sup>23,27-31</sup>

Novel treatments proposed for optic disc pit maculopathy include macular scleral buckling and vitrectomy with inner retina fenestration.<sup>2</sup> Both methods have been reported to produce favorable anatomical and functional results. However, there has not been widespread adoption of these techniques. Optic nerve sheath decompression has also been reported to treat retinal detachments associated with morning glory disc anomaly, although its exact role is uncertain.<sup>16</sup>

Silicone oil should be avoided in eyes with excavated defects of the optic nerve. Migration of intraocular silicone oil into the subretinal space and even the subarachnoid space has been reported to occur in eyes with an optic disc pits. In the case of subarachnoid migration, central nervous system related symptoms occurred.<sup>32,33</sup>

## OTHER OPTIC NERVE ABNORMALITIES ASSOCIATED WITH MACULAR PATHOLOGY

### Optic Nerve Abnormalities Associated With Choroidal Neovascularization

A number of optic nerve abnormalities have been associated with peripapillary choroidal neovascularization (CNV), including optic disc pits (Fig. 6.36.9), morning glory disc anomaly, retinochoroidal coloboma involving

the optic nerve, tilted disc syndrome, optic disc drusen; papilledema; and papillitis secondary to idiopathic multifocal chorioretinitis. It is believed that in these cases, new vessel growth is influenced by disruption of the choroid, RPE, and Bruch's membrane.<sup>34</sup>

Peripapillary CNV related to optic nerve abnormalities is uncommon. Our knowledge regarding the prognosis and management of peripapillary CNV has been derived, mainly, from studying peripapillary CNV secondary to macular conditions independent of optic nerve abnormalities.<sup>35</sup>

Thermal laser therapy was the first intervention described for peripapillary CNV. The guidelines were derived from the Macular Photocoagulation Study (MPS). Many advocate treatment of peripapillary CNV prior to it extending within 2500 microns from the center of the foveola.<sup>35</sup> The morbidity associated with such treatment is lower than that associated with extension of the neovascularization and associated sequelae into the fovea. A wide margin of photocoagulation to normal tissue around the edge of any angiographic abnormality is recommended. According to the MPS guidelines, patients are considered ineligible for laser treatment if the lesion is >4.5 clock hours; a large adjacent submacular hemorrhage is present; and 1.5 clock hours of temporal peripapillary retina is not spared.<sup>35</sup> Cases of peripapillary CNV secondary to bilateral optic nerve drusen and retinochoroidal colobomas have been successfully treated with laser photocoagulation.<sup>36</sup>

Photodynamic therapy (PDT) with verteporfin results in less local tissue damage than use of a thermal laser. The successful treatment of peripapillary CNV associated with optic nerve head drusen using PDT has been reported.<sup>36</sup> It is controversial whether the PDT treatment field can include the optic nerve. There are concerns about optic nerve damage if the PDT laser spot extends closer than 200 microns from the edge of the optic nerve. However, in treating peripapillary CNV, several investigators have included part of the optic disc within the PDT field without complication.<sup>35</sup>

Surgery has also been described for the treatment of patients with peripapillary CNV. One patient with peripapillary CNV secondary to optic nerve head drusen showed recovery without recurrence following subretinal membrane removal.<sup>37</sup>

Anti-vascular endothelial growth factor (anti-VEGF) agents are most commonly used in the treatment of neovascularization from a variety of causes. Anti-VEGF treatment is advantageous because it can preserve the papillomacular bundle and can be useful in cases where proximity of the lesion to the fovea precludes other treatment modalities.

Anti-VEGF agents alone or combined with photocoagulation have been described for the treatment of peripapillary CNV secondary to optic nerve head drusen. In all cases, treatment resulted in anatomical and functional improvement.<sup>36,38</sup>

## Abnormalities Associated With Exudation

Abnormalities that cause papillitis can lead to severe chronic leakage of plasma and lipid products that extend into the central macula. The lipid is located within the outer plexiform layer (Henle's fiber layer) and often has the configuration of a hemi- or full macular star (Fig. 6.36.10). When this hard exudate is present, retinal thickening (macular edema) is often seen concomitantly. FA shows leakage of the optic nerve vessels without leakage of the macular vessels. The exudates appear as hyperreflective foci in the outer plexiform layer on OCT and have decreased autofluorescence on imaging.<sup>39</sup>

The specific entities that can cause papillitis and subsequent hard exudation into the macula include idiopathic optic neuritis (Leber's stellate optic neuropathy), sarcoidosis, infectious neuroretinitis, idiopathic intracranial hypertension, malignant hypertension, radiation optic neuropathy, and anterior ischemic optic neuropathy. In infectious neuroretinitis, the macular star becomes prominent over first 3 weeks, and the neuroretinitis resolves over 6–8 weeks. When the underlying cause is systemic arterial hypertension, resolution of the hard exudate usually occurs within weeks to months after the blood pressure returns to normal.<sup>40</sup>

The most common causes of infectious neuroretinitis include *Bartonella henselae* infection, Lyme disease, and syphilis. Infectious causes are

**Fig. 6.36.10** Unilateral optic disc edema and associated macular star pattern of hard exudates in a 9-year-old girl with neuroretinitis secondary to infection by *Bartonella henselae*.

usually unilateral and may be associated with mild vitritis. *B. henselae* is the causative organism of cat scratch disease, and diagnosis can be supported by serum antibody titers. It may take 4–6 weeks for seroconversion to occur. In seronegative cases, repeat serology is recommended in 2 months.<sup>39</sup> Other macular abnormalities associated with cat scratch disease include macular edema, focal chorioretinitis and choroidal infiltrates, vasculitis, vascular occlusions, and subretinal angiomatous lesions.<sup>39</sup>

No specific treatment is indicated for these exudative maculopathies other than alleviation of the underlying problem, when possible. In cases of *B. henselae* infection, the prognosis is usually good even without treatment. Treatment options include 4–6 weeks of doxycycline with rifampin, systemic gentamicin, trimethoprim–sulfamethoxazole, or ciprofloxacin. The role of corticosteroids is not known.<sup>40</sup>

## Peripheral Retinal Lesions

William Tasman<sup>†</sup>

6.37

**Definition:** A heterogeneous group of anatomical variations, degenerative changes, and pathological processes that can be observed ophthalmoscopically in the anterior neural retina and ora serrata region.

**Key Features**

- Anatomical variations in the anterior neural retina and ora serrata region.
- Degenerative changes in the anterior neural retina and ora serrata region.
- Pathological processes in the anterior neural retina and ora serrata region.

**Associated Features**

- Best observed with indirect ophthalmoscopy and scleral depression.
- Contact lens examination may assist.
- Possible association with premature vitreous collapse and retinal detachment.
- Usually stable over time.

**INTRODUCTION AND ANATOMY**

Many variations occur in the ophthalmoscopic appearance of the peripheral neural retina. In most cases, these variations are not of clinical significance; however, certain anatomical changes can render eyes at higher risk for retinal breaks and rhegmatogenous retinal detachment.

The fundus may be roughly separated into central (posterior) and peripheral (anterior) portions by a circle that passes through the posterior edge of the scleral entrance of each vortex vein ampulla. The anatomical equator is located approximately two disc diameters (3 mm) anterior to the entrance of the scleral canals. Thus, the vortex veins become important landmarks when separating the peripheral fundus from the posterior pole.

The fundus also may be divided by natural features into superior and inferior halves by the long ciliary nerves and arteries that form a horizontal boundary nasally and temporally.<sup>1</sup>

In the peripheral fundus, it often is difficult or impossible to distinguish between arterioles and venules on the basis of size, color, or pattern.<sup>2</sup> The most practical method of identification is to trace the vessels back to the posterior fundus. The retinal arterioles and venules generally do not course together but are evenly distributed throughout the periphery. Most of them become very small and disappear before reaching a distance of 0.5 disc diameter from the ora serrata. The arterioles disappear first, whereas the venules tend to extend closer toward the ora serrata.

**Ora Serrata**

In the ora serrata region, the retina becomes opalescent and often is marked by small rows of cystoid cavities.<sup>3</sup> This is normal. Extensive cystoid changes do not represent pathology. The underlying pigment epithelium appears darker and more granular than that seen posteriorly. The neural retina stops abruptly at the ora serrata and is continued by the nonpigmented ciliary epithelium, which appears considerably thinner than the retina. The pars plana corporis ciliaris is more deeply pigmented than the peripheral retina, and thus the choroidal pattern is obscured by that of the pigment epithelium. The development of the ora serrata is incomplete at birth and continues during early life.<sup>4,5</sup>

Because ora bays and teeth (or dentate processes) frequently are difficult to identify temporally, the exact number of ora teeth is not easy to calculate. Salzmann,<sup>5</sup> in 1912, identified 48, whereas Straatsma et al.<sup>6</sup> noted 16 dentate processes along the average ora serrata. In the chapter author's experience, the number varies, but usually between 20 and 30 dentate processes can be counted reliably, corresponding in position to the intervals between the ciliary processes.

**Vitreous Base**

One of the most significant structures in the peripheral fundus is the vitreous base. It is of clinical importance because retinal breaks frequently occur along its posterior border and, in the case of traumatic detachment, occasionally along the anterior border, as well.<sup>7</sup> The vitreous base involves the full circumference of the peripheral fundus and measures approximately 3.2 mm in width. Generally, it is wider nasally than temporally and may have an irregular posterior border (Fig. 6.37.1). It represents an area in the fundus in which the vitreous, neural retina, and pigment epithelium all are firmly adherent, one to the other. It is for this reason that in some cases of traumatic detachment, the vitreous base is avulsed with its underlying neural retina and pigment epithelium, to create a retinal dialysis and a "garland" that hangs down into the vitreous cavity (Fig. 6.37.2). The vitreous base may be prominent in some individuals, especially those with a darkly pigmented choroid.

The pars plana is delineated at its posterior margin by the ora serrata. The sensory retina continues into the pars plana as the nonpigmented ciliary epithelium. The vitreous base, which straddles the ora serrata, has its anterior border in the pars plana, where it parallels the configuration of the ora serrata.

**OCULAR MANIFESTATIONS AND DIAGNOSIS OF PERIPHERAL RETINAL LESIONS****Meridional Folds or Radial Folds**

Meridional folds, or radial folds, which usually involve all neural retinal layers, are a common, normal variant seen in the peripheral fundus. As a

**Fig. 6.37.1** The anterior border and posterior border of the vitreous base. The posterior border is irregular. Areas of paving stone degeneration that extend across the ora serrata into the pars plana can also be seen.

<sup>†</sup>Deceased

**Fig. 6.37.2** Avulsed vitreous base.

**Fig. 6.37.3** Meridional fold with a small break at the base of the fold.

rule, a meridional fold begins in the ora serrata and runs posteriorly and perpendicularly to it in a meridional fashion. It is a radially aligned elevation of the peripheral retina and may be associated with retinal breaks (Fig. 6.37.3). Meridional folds are found significantly more often nasally than temporally and especially in the upper nasal quadrant.<sup>3,8</sup> They are found in 20% of eyes examined during autopsy.<sup>9</sup> In cases of rhegmatogenous retinal detachment, the posterior edges of meridional folds must be examined carefully for retinal breaks.

### Pars Plana Cysts

Cysts of the pars plana corporis ciliaris are another variant seen in the fundus periphery.<sup>10</sup> These consist of a clear cystoid space between the pigmented and nonpigmented epithelia located anterior to the ora serrata (Fig. 6.37.4). The cysts, which have the appearance of half-inflated balloons, lie between the pars plana radiations. Generally, the overlying vitreous and its surrounding ciliary pigment epithelium remain unchanged. Occasionally, patients who are highly myopic demonstrate a marked degree of cyst formation along the entire pars plana.

### Ora Serrata Pearls

Still another change that may be noted in the fundus periphery is the ora serrata pearl. This glistening opacity (Fig. 6.37.5A, B), which usually forms over an oral tooth, varies from pinpoint to pinhead in size.<sup>11</sup> It appears in all age groups but increases significantly in incidence with advancing age.<sup>12</sup> Pearls are not related to other fundus pathology and are probably of developmental origin. They occur throughout the ora serrata region and are drusen-like structures that show the staining qualities of an acid carbohydrate on pathological examination.

**Fig. 6.37.4** Pars plana cysts. The radial striations can also be seen directed between the ciliary processes. (Courtesy Dr. Ralph Eagle, Jr.)

**Fig. 6.37.5** (A) Ora serrata pearl. (B) The pearl lies on an oral tooth. Again, radial striations are directed between the ciliary processes.

### Degenerative Adult Retinoschisis

Degenerative retinoschisis usually is bilateral, often symmetrical, and commonly bullous. It frequently first appears in the inferotemporal quadrant and may be slowly progressive.

**Fig. 6.37.6** (A) Outer layer breaks. (B) Over a 3-year period, pigmentation developed around the breaks.

Bullous types of retinoschisis appear clinically as thin, elevated layers of tissue, best observed in the inferotemporal periphery. The retinal vessels often are sheathed terminally, and fine white spots may occur on the inner surface. These represent the Müller fibers that traverse the schisis cavity.

Large outer layer holes may develop over time, often with a rolled edge (Fig. 6.37.6A). Pigmented demarcation lines are not a clinical feature of bullous retinoschisis. If present, they usually suggest long-standing non-progressive retinal detachment. However, over time, pigmentation around the break(s) may occur, indicating localized retinal detachment which can be monitored (see Fig. 6.37.6B).

The major complication of retinoschisis is retinal detachment. In 987 patients with retinal detachment followed up by Pecold et al.,<sup>13</sup> retinoschisis was present in 25, an incidence of about 2.5%. Retinal detachment occasionally may occur when holes exist in the outer layer of the schisis. In many cases, inner layer holes also occur, but these need not be present for retinal detachment to develop. The detachment may gradually extend beyond the area of retinoschisis, in which case it may resemble a typical rhegmatogenous detachment.<sup>14</sup> When progression of the schisis toward the posterior pole extends posterior to the equator, perimetry reveals an absolute field defect, whereas the defect associated with retinal detachment is relative.

Byer<sup>15</sup> conducted a long-term natural history study of 123 consecutive, unselected patients (218 eyes) who had suffered acquired retinoschisis for 1–21 years (average 9.1 years), to ascertain the natural behavior and prognosis of this disease and formulate reasonable recommendations for

**Fig. 6.37.7** Clinical picture of lattice degeneration showing the typical white lines. These lines represent hyalinized vessels.

its management. The quadrant of maximal involvement was the inferior temporal, and 74% of the lesions had postequatorial posterior borders. Most importantly, degenerative retinoschisis was found to be primarily asymptomatic and nonprogressive. No case of symptomatic progressive retinal detachment occurred, but 14 cases of localized, nonprogressive, and asymptomatic schisis–retinal detachment were noted.

Byer<sup>16</sup> concluded that the only indication for treatment of a schisis is the symptomatic or progressive schisis–retinal detachment that threatens the macula. Laser demarcation of a schisis or treatment of the borders of outer layer retinal breaks should be avoided.<sup>15–17</sup>

## Congenital X-Linked Retinoschisis

Congenital X-linked schisis is characterized by a stellate macular appearance and, often, large nerve fiber layer dehiscentes. Optical coherence tomography (OCT), however, has shown that the split may, in some instances, involve more than just the nerve fiber layer.

## Paving Stone Degeneration

Paving stone degeneration is a chronic, slowly progressive disorder that usually does not produce any symptoms or complications. It is seen more commonly in older patients and is bilateral in one third of the cases.<sup>18</sup>

Paving stone degeneration is characterized by well-delineated, flat yellow foci in the size range of 0.5–2.0 disc diameters (see Fig. 6.37.1). Irregular black pigmentation frequently is present on the margins of the lesions and red lines, which correspond to choroidal blood vessels, may traverse them. With time, the individual lesions may become confluent and form a continuous band of irregular pigment clumping. Although paving stone degeneration may be located in any quadrant, it is most common inferiorly between the equator and the ora serrata but may extend into the pars plana.

## Lattice Degeneration and Retinal Breaks

In contrast to the conditions previously described, lattice degeneration has greater clinical significance.<sup>19</sup> It is especially important because of its relationship to rhegmatogenous retinal detachment.

Ophthalmoscopically, lattice degeneration appears as one or more linear bands of retinal thinning located in the equatorial region (Fig. 6.37.7). Fine white lines, which account for the term *lattice degeneration*, are present in only about 9% of lesions.<sup>20</sup> Pigmentary disturbances within the band of retinal thinning, however, are present in most cases. Occasionally, lesions separating vascularized from avascular retina may simulate lattice, especially in familial exudative vitreoretinopathy, as can be seen in Fig. 6.37.8.

Using “A” scan axial length measurement, the prevalence of lattice was greater in eyes without staphyloma, in which the whole eye was elongated, versus eyes with staphyloma, in which only the posterior pole was elongated.<sup>20</sup>

**Fig. 6.37.8** Ridge between the vascularized and avascular retina in familial exudative vitreoretinopathy may be confused with lattice.

With lattice degeneration, the vitreous gel is attached firmly to the margin of the lesion. Usually, a clear pocket of liquid vitreous is present over the central thin portion of each lesion.

Retinal holes often can be observed in lattice degeneration. Two types of breaks have been recognized. Round or atrophic holes usually are found centrally within the thin portion of the lesion and usually are not associated with vitreous traction. These may lead to retinal detachment in young patients with myopia. Horseshoe-shaped breaks occur most commonly on the posterior edge of the lesion and are associated with severe vitreous traction (Fig. 6.37.9).

Lattice degeneration of the retina is present in about 7%–8% of adult eyes.<sup>21–24</sup> Burton<sup>21</sup> showed that patients with lattice degeneration, ages 40–60 years, and with low to moderate degrees of myopia tend to develop detachments caused by premature posterior vitreous detachment (PVD) and traction tears. However, he pointed out that prophylaxis for this group is not warranted because only 5%–10% will experience PVD during their lives.

Furthermore, up to one fourth of symptomatic acute PVDs show incomplete separation, which may lead to delayed retinal breaks and/or epiretinal membranes.<sup>23–27</sup>

In an evidence-based analysis of prophylactic treatment of asymptomatic retinal breaks and lattice degeneration, a panel of vitreoretinal experts reviewed the English language literature.<sup>27</sup> They concluded that there was insufficient information to strongly support prophylactic treatment of lesions other than symptomatic flap tears.

# Retinal Breaks

Margaret A. Greven, Craig M. Greven

# 6.38

**Definition:** A full-thickness defect in the neurosensory retina.

## Key Features

- A round, oval, or horseshoe-shaped defect.
- Typical location near the vitreous base, but can occur anywhere.
- Subcategories are holes, tears, or dialyses.

## Associated Features

- Pigmented cells in the vitreous (tobacco dust).
- Vitreous traction.
- Vitreous hemorrhage.
- Pigmentary changes in the adjacent retina.
- Localized abnormal vitreous–retinal interface (lattice degeneration).

## INTRODUCTION

Retinal breaks are full-thickness defects in the neurosensory retina. They typically occur in the equatorial and ora serrata regions of the retina but can develop more posteriorly as well. Peripheral retinal breaks do not cause loss of vision, but the associated conditions of vitreous hemorrhage and rhegmatogenous retinal detachment can cause severe visual loss. The first goal in the management of retinal breaks is to differentiate those not likely to cause severe visual sequelae from those more likely to lead to visual loss and retinal detachment. In this chapter, the identification of “high-risk” retinal breaks is discussed, and appropriate management strategies are suggested.

## EPIDEMIOLOGY AND PATHOGENESIS

The incidence of retinal breaks at autopsy in individuals age >20 years is in the range 6%–11%.<sup>1,2</sup> The prevalence of retinal breaks in clinical series of routine patients aged ≥10 years without antecedent ocular disease ranges from 6%–14%.<sup>3,4</sup> The annual incidence of retinal detachment is approximately 12 per 100 000 population per year.<sup>5,6</sup> From these data, it is intuitive that most retinal breaks do not lead to detachment. Therefore, it has been the goal of clinicians to determine which breaks may benefit from prophylaxis.

The occurrence of retinal breaks is age dependent, with increasing incidence accompanying increasing age. However, no statistical difference exists between men and women in the incidence of retinal breaks.<sup>1,3</sup> The prevalence of retinal breaks in myopic eyes is similar to that in eyes of the general population, about 11%.<sup>7</sup> However, cases of myopia account for 42% of all cases of phakic retinal detachments, and, therefore, myopia is considered a risk factor for retinal breaks that lead to retinal detachment.<sup>8</sup>

Lattice degeneration of the retina is another risk factor for the development of retinal breaks. Lattice degeneration is a condition in which peripheral retinal thinning is associated with liquefaction and separation of the overlying vitreous, and a pronounced vitreoretinal adhesion at the margin. Lattice is found on autopsy in 11% of cases, occurs equally in men and women, and increases in incidence with increasing age.<sup>9</sup> It is a bilateral condition in nearly 50% of cases, and approximately 25% of affected eyes have associated retinal breaks.

Ocular contusion and penetrating trauma also increase the risk for development of a retinal break. The most common type of retinal break after ocular contusion injuries is a retinal dialysis.<sup>10,11</sup> Penetrating trauma

may cause retinal breaks immediately at the time of impact, because of direct retinal trauma, or as a result of later vitreous traction.

## OCULAR MANIFESTATIONS

### Retinal Tears

Retinal tears are full-thickness breaks that occur secondary to vitreous traction. The most common inciting vitreous traction is spontaneous posterior vitreous detachment (PVD). These horseshoe or flap tears occur at sites of strong vitreoretinal adhesion, most commonly at the vitreous base. The posterior edge of the tear is its apex, and the anterior extensions are its base (Figs. 6.38.1 and 6.38.2). Symptoms associated with acute horseshoe tears include floaters secondary to vitreous debris (hemorrhage, retinal pigment epithelium [RPE] cells) and flashes that result from persistent vitreous traction.

Firm vitreoretinal adhesions are present at the margins of lattice degeneration. When a PVD occurs, traction at the margin of the lattice degeneration can lead to retinal tears. These tears typically occur at the posterior or lateral margin of a patch of lattice.

### Round Holes With Opercula

Horseshoe or flap tears with persistent traction often avulse the base of the tear to leave a small, round defect in the neural retina with an overlying operculum of retinal tissue. This generally indicates complete relief of vitreoretinal traction in this area (Fig. 6.38.3).

### Round Holes Without Opercula (Atrophic Holes)

Atrophic holes in the retina occur secondary to retinal thinning. Vitreous traction is not the pathogenic mechanism of atrophic retinal holes. Although these can occur in isolation, they often present within areas of lattice degeneration.

### Traumatic Retinal Breaks

Blunt trauma to the globe can induce a variety of retinal breaks, which include horseshoe tears, retinal dialysis, and macular holes. The major mechanism of peripheral break formation is hypothesized to be compression of the globe with subsequent distortion and expansion at the area of the ora serrata and equator. This expansion produces an acute increase in vitreoretinal traction, which often results in a retinal dialysis.<sup>11</sup> Traumatic retinal dialyses most commonly occur inferotemporally and superonasally.<sup>12</sup> Direct contusion injury to the globe can lead to disruption of the retina and necrotic breaks. The retinal defects are typically irregular and located in the region of the vitreous base.

## DIAGNOSIS AND ANCILLARY TESTING

When the media is clear, retinal breaks can be diagnosed with indirect ophthalmoscopy or contact lens examination. In the setting of cloudy media, ultrasonography may detect the presence of retinal breaks, and ultrasound-guided cryotherapy can be utilized.<sup>13</sup>

## DIFFERENTIAL DIAGNOSIS

Many conditions in the peripheral fundus can mimic full-thickness retinal breaks. Obstacles to an accurate diagnosis include inadequate pupillary dilatation, cataract, anterior and posterior capsular opacities in pseudophakic eyes, vitreous opacities, and patient compliance. Binocular indirect

**Fig. 6.38.1 Symptomatic Acute, Superotemporal Horseshoe Tear Anterior to the Equator in the Right Eye.** (A) At presentation. Note the hemorrhage at its margins. (B) The same eye 1 week after cryopexy. Note the affection of retinal pigment epithelium adjacent to the tear.

ophthalmoscopy with scleral depression to see the retina in relief, supplemented by Goldmann three-mirror examination, remains the standard method to differentiate these lesions. The differential diagnosis of retinal breaks is given in [Box 6.38.1](#). (See Chapter 6.37 for a more detailed discussion.)

## SYSTEMIC ASSOCIATIONS

The majority of retinal breaks occur in patients who have no predisposing systemic association. However, certain systemic conditions, such as Marfan's syndrome, Ehlers–Danlos syndrome, and homocystinuria, as well as hereditary hyaloideoretinopathies, such as Wagner's syndrome and Stickler's syndrome, can predispose to retinal break formation (see Chapter 6.15).

## TREATMENT OF RETINAL BREAKS

Upon discovery of a retinal break, the initial decision is whether the benefits of treatment (to prevent retinal detachment) outweigh the risks and cost of treatment. In each case, many factors should be considered

**Fig. 6.38.2** Symptomatic inferior horseshoe tear 6 weeks after cryopexy.

and the risks and benefits of treatment discussed with the patient. The factors under consideration in each case include the presence or absence of symptoms; age and systemic health of the patient; refractive error of the eye; location, age, type, and size of the break; status of the fellow eye; and whether the patient has aphakia or pseudo-phakia or is scheduled to undergo cataract surgery.

The typical symptoms associated with an acute retinal break are new floaters and flashes. These symptoms occur secondary to an acute PVD. Studies have shown that the presence or absence of symptoms in association with the onset of the break is the most important prognostic criterion for progression to retinal detachment.<sup>14-16</sup> In a prospective study of 359 asymptomatic retinal breaks in 231 phakic eyes of 196 patients, no clinical retinal detachment had occurred after a minimum 1-year follow-up.<sup>14</sup> Included in this study were 276 round atrophic holes, 50 tears with attached flaps, and 33 tears with free opercula. In phakic patients with no previous history of retinal disease or high myopia and who develop asymptomatic horseshoe tears, atrophic holes, or holes with opercula, prophylactic treatment is rarely indicated. In each case, the patient should be made aware of the symptoms of vitreous traction and retinal detachment and should be instructed on how to assess the peripheral visual field. To date, no randomized clinical trial has been performed to support conclusions regarding the value of treating asymptomatic retinal breaks.<sup>17</sup> In contrast, the rate of retinal detachment in phakic patients who have symptomatic breaks is 35%.<sup>15</sup> Therefore, it is recommended that all acute, symptomatic retinal breaks be treated to prevent retinal detachment.

Age and systemic health status of the patient are other variables to be considered in the management of a retinal break. As an example, a superotemporal horseshoe tear in a 27-year-old patient is more likely to cause a subsequent retinal detachment than is one in an 80-year-old patient who has metastatic lung cancer. Refractive error is considered in the management of retinal breaks. The increased incidence of retinal detachment in patients who have  $>-6.00$  diopters (D) of myopia may increase the likelihood for treatment of an asymptomatic retinal tear.

The age of the patient and the location and size of a retinal break are also considered when its management is determined. Long-standing tears often have RPE changes adjacent to them. These changes reflect chorio-retinal adhesion and indicate to the clinician the decreased likelihood of retinal detachment. Although no increased incidence of retinal detachment occurs with a retinal break in any particular quadrant, a greater likelihood of a macula-off retinal detachment is present as a result of superotemporal breaks than of either inferior breaks or nasal breaks. Although small retinal breaks can lead to retinal detachment, most ophthalmologists agree that, in general, larger breaks are more likely to cause retinal detachment.

The type of break should be a consideration in whether prophylactic treatment is offered. A horseshoe tear with persistent traction or a retinal dialysis is much more likely to result in a detachment compared with an atrophic hole.

Some controversy exists about the management of asymptomatic horseshoe tears in patients who need cataract surgery, in patients with aphakia or pseudophakia, and in patients who have retinal detachments in their

**Fig. 6.38.3 Symptomatic Operculated Hole.** (A) At presentation. (B) Immediately after laser treatment. (C) 1 month postoperatively. Operculum is best seen in part C.

### BOX 6.38.1 Differential Diagnosis of Retinal Breaks

- Pars plana cysts
- Enclosed oral bays

- Granular tags
- Paving stone degeneration
- Chorioretinal scars
- Peripheral cystoid degeneration
- White with/without pressure
- Retinal erosions
- Vitreous condensation

fellow eye.<sup>17-19</sup> In general, because of the increased incidence of detachment in these scenarios, strong consideration should be given to prophylaxis in these cases.

Retinal dialyses, whether traumatic or idiopathic, have a high association with the development of retinal detachment. In these cases, prophylaxis is usually indicated.

Asymptomatic holes in lattice degeneration rarely lead to detachment and usually receive no prophylaxis.<sup>20</sup> However, retinal tears at the margin of lattice degeneration, particularly in symptomatic eyes, are more likely to result in the development of a retinal detachment and require prophylactic therapy. Prophylactic treatment should be considered in patients with lattice degeneration who have had a retinal detachment in the fellow eye.

### Cryopexy

Cryotherapy is delivered transconjunctivally. It destroys the choriocapillaris, RPE, and outer retina to provide a chorioretinal adhesion between the tear and the adjacent retina, thus preventing liquid vitreous access through the hole and into the subretinal space. The adhesion with cryotherapy is not immediate; a period of 1 week is required to achieve partial adhesion and up to 3 weeks for the full adhesive effects to occur.

Under indirect ophthalmoscopic visualization, the cryoprobe is placed on the conjunctiva that overlies the break, and cryotherapy is delivered until the retina adjacent to the tear becomes gray-white. Approximately 2 mm of retinal whitening should be obtained around the entire break. Applications are placed until the break is surrounded completely with confluent treatment (see Figs. 6.38.1 and 6.38.2). In horseshoe tears, the anterior retina between the tear and the ora serrata should be treated, as anterior extension of the tear secondary to continuous vitreous traction can lead to retinal detachment. Cryopexy can be delivered adequately despite the presence of extensive cataract, anterior or posterior capsular opacity, or relatively dense vitreous hemorrhage.

### Photocoagulation

Laser photocoagulation treatment of retinal breaks typically utilizes the argon green or diode laser. Two main delivery systems are used: the slit lamp and the indirect ophthalmoscope. In contrast to cryotherapy, chorioretinal adhesion occurs the instant that the laser photocoagulation is applied, but maximal adhesion occurs 7–10 days later.

The Goldmann three-mirror lens or panfunduscope lens is used when treatment is with slit-lamp delivery. The tear should be surrounded completely by 3–4 rows of laser burns. Although the spots need not be confluent, there should be no more than half a spot size of untreated retina between burns. Typically, the settings are 200–500 mm spot size and 0.1–0.2 second application at the power necessary to generate a gray-white burn. Treatment with the diode laser with long duration and larger spot size can be successfully utilized.<sup>21,22</sup> The indirect laser delivery system can also be used to treat retinal breaks (Fig. 6.38.4). An advantage of this technique is that simultaneous scleral depression allows treatment of anterior tears and even dialysis.

As with cryopexy, care should be taken to thoroughly treat the anterior margin of horseshoe tears to prevent anterior traction that reopens the break.

### Anesthesia

Eyes that undergo laser photocoagulation can often be treated with topical anesthesia alone. If multiple large breaks are present and the patient is

**Fig. 6.38.4** Wide angle fundus imaging showing retinal tear immediately after laser retinopexy.

unable to tolerate the treatment, retrobulbar anesthesia may facilitate completion of the procedure. In patients treated with transconjunctival cryotherapy or indirect laser photocoagulation with scleral depression, topical anesthesia may be supplemented with placing cotton-tipped applicators soaked in 4% lidocaine on the conjunctiva that overlies the retinal breaks. In some cases, 2% lidocaine injection subconjunctivally via a 30-gauge needle may be necessary.

## COURSE AND OUTCOME

The eye is typically examined a few weeks following treatment. Although vigorous patient activity is often discouraged initially, no clinical study has documented that diminished activity improves treatment results. A firm chorioretinal adhesion is present by 3 weeks after either technique.

Failure rates for prophylactically treated retinal breaks depend on many factors, which include the type of retinal break, indications for treatment,

length of follow-up, and definition of failure. Reported failure rates range from 0%–22%.<sup>23,24</sup> In one large series of prophylactically treated retinal breaks, 22% of eyes required an additional procedure to prevent or repair a retinal detachment.<sup>24</sup> Risk factors for failure in this series included aphakic or pseudophakic status, acute symptoms, retinal detachment in the fellow eye, and male gender.

Epiretinal membrane and macular pucker are other visually significant complications associated with prophylactic treatment of a retinal break; they occur in 1%–5% of treated eyes.<sup>24,25</sup> As epiretinal membranes occur in eyes that have retinal breaks and receive no treatment, it is not entirely clear whether the macular pucker is exacerbated by the treatment modality or is solely a result of the disease process itself.

More rare complications that can occur include Adie's pupil, subretinal and vitreous hemorrhage, and breaks in Bruch's membrane. An exceedingly rare but potentially devastating complication of cryotherapy in patients who have staphylomatous sclera is scleral rupture.

In eyes that fail prophylactic therapy, retinal detachment repair by pneumatic retinopexy, scleral buckling, or vitrectomy is usually successful in the anatomic reattachment of the retina.

**Definition:** Separation of the neural retina from the underlying retinal pigment epithelium (RPE) as a result of vitreous passing through a retinal defect into the subretinal space.

## Key Features

- Elevation and separation of the neural retina from the underlying RPE.
- One or more retinal breaks (holes, tears, or dialyses).

## Associated Features

- Vitreous liquefaction.
- Posterior vitreous detachment ("complete" or partial).
- Vitreoretinal traction.
- Vitreous cells (pigment and/or hemorrhage).
- Flashes (photopsia) and floaters.
- Scotoma corresponding to the area of retinal elevation.

## INTRODUCTION

Rhegmatogenous retinal detachment (RRD) is an important cause of visual disability. Untreated, symptomatic RRDs generally progress to total blindness. Prompt recognition of the associated symptoms helps ensure timely treatment and sustain useful vision. Environmental and hereditary factors play significant roles in RRD development. Knowledge of these diverse features helps identify high-risk patients.

## EPIDEMIOLOGY AND PATHOGENESIS

The incidence of RRD ranges from 5.3–12.6 cases per 100 000.<sup>1</sup> RRD is defined as egress of vitreous into the potential subretinal space between the neural retina and the RPE via a retinal break (rhegma = rent or rupture). Pathogenesis of this entity arises from vitreous collapse (syneresis) and liquefaction (synchysis) as a result of degenerative changes in the collagen fibril-hyaluronan matrix, which leads to posterior vitreous detachment (PVD) and focal retinal traction.<sup>2</sup> Vitreous traction can produce retinal breaks, most commonly in the peripheral retina, where the vitreous base remains most adherent to retina (Fig. 6.39.1). Liquefied vitreous migrates from the intravitreal cavity to dissect into the subretinal space, causing scotomata. Fluid currents related to eye movements can extend the detachment into the macula, leading to central vision loss, the main morbidity associated with RRD.

## Factors Causing Retinal Detachment

Vitreous syneresis, synchysis, and PVD are the chief factors in RRD; indeed, conditions in which these events occur prematurely are associated with a higher risk of RRD. However, the majority of eyes with retinal breaks do not develop retinal detachment because normal physiological forces keep the retina in place. Retinal attachment is maintained by the following<sup>3</sup>:

- An interphotoreceptor matrix in the subretinal space.
- Oncotic pressure differences between the choroid and subretinal space.
- Hydrostatic or hydraulic forces related to intraocular pressure.
- Metabolic transfer of ions and fluid by the RPE.

**Fig. 6.39.1 Classic Pathogenesis of Rhegmatogenous Retinal Detachment (RRD).** The detached vitreous gel has caused a retinal tear by exerting traction on the retina at the site of a vitreoretinal adhesion. Liquid in the vitreous cavity passes through the break into the subretinal space. (Courtesy Charles P. Wilkinson.)

Retinal detachment occurs when the combination of factors that promote retinal detachment overwhelms the normal attachment forces.

## Retinal Breaks

The nature of the vitreoretinal adhesion associated with the retinal break remains the principal consideration in determining progression to RRD and choice of treatment. A retinal hole is a round, full-thickness defect. In this case, vitreoretinal traction is generally relieved, sometimes in the presence of an overlying operculum. A retinal hole is less likely to progress to a RRD and is generally observed (Fig. 6.39.2). A full-thickness retinal break with persistent vitreoretinal traction, such as a retinal flap tear, is more likely to progress to RRD and is generally treated with laser or cryoretinopexy (see Fig. 6.39.2).

Dialyses are linear or circumferential retinal breaks that occur along the ora serrata. Although most are associated with blunt ocular trauma, dialyses can occur spontaneously.

## Vitreous Liquefaction and Detachment

The degeneration of the collagen-hyaluronan matrix of the vitreous results in liquefaction at multiple sites, forming lacunae. Progressive liquefaction, shrinkage, and coalescence of lacunae eventually lead to vitreous collapse

**Fig. 6.39.2 Retinal Detachment.** Retinal tears are caused by vitreoretinal traction. Persistent traction frequently causes extensive retinal detachment (on left). If the traction results in a break that is not associated with persistent vitreoretinal traction (on right), the tear acts as a retinal hole and detachment is quite unlikely. (Courtesy Charles P. Wilkinson.)

**Fig. 6.39.3 Separation of the Posterior Cortical Vitreous.** An acute event, posterior vitreous detachment usually begins with an apparent break in the cortical vitreous that overlies the macula. Fluid from a central lacuna flows through this hole and separates the cortical vitreous from the retina. (Courtesy Charles P. Wilkinson.)

and, in turn, to PVD. Intravitreal fluid then egresses from lacunae to fill the potential space between the posterior vitreous and retinal surface (Fig. 6.39.3). Interestingly, some authorities consider PVD to actually be vitreous schisis because cortical vitreous often remains adherent to the retina.<sup>4</sup> The mechanism of progression of a partial PVD to a “complete PVD” (vitreous attached only at the vitreous base) is not fully understood, but it can be rapid (within several weeks). Regardless of the type of separation, the vitreous exerts asymmetrical tractional forces at regions where vitreous is most adherent, such as the vitreous base, a common site for formation

of retinal breaks. Conditions associated with early vitreous liquefaction and detachment, such as pathological myopia, surgical and nonsurgical trauma, intraocular inflammation, and a variety of other congenital, inherited, or acquired ocular disorders, are associated with a higher risk of RRD.

### Traction on the Retina

The mechanisms of vitreoretinal traction vary. Progressive syneresis can cause shrinkage and collapse of the gel with accompanying traction at points of contact with the retinal surface, causing full-thickness retinal breaks and entry points for subretinal egress of intravitreal fluid. Rotational and saccadic eye movements may also play a role.<sup>5</sup> When the eye rotates, the inertia of the detached vitreous gel causes it to lag behind the rotation of the eye wall and the attached retina. The vitreous gel, because of its inertia, exerts an equal and opposite force on the retina, which can cause a retinal break or separate the neural retina farther from the pigment epithelium if subretinal fluid is already present (Fig. 6.39.4). At areas where vitreous remains attached to the retina, such as a horseshoe tear flap at the vitreous base, eye movements allow asymmetrical traction at the flap, holding it “open” while liquefied vitreous migrates into the subretinal space, allowing enlargement of retinal detachment (Fig. 6.39.5). When the rotational eye movement stops, the vitreous gel continues its internal movement and exerts vitreoretinal traction in the opposite direction.

In combined, tractional–RRDs, contractile fibrovascular membranes that occur in uveitic disorders, trauma, retinopathy of prematurity, proliferative diabetic retinopathy, retinovascular disorders, and other ischemic retinopathies, can create a retinal break.

### Liquid Currents

The development of an RRD requires that fluid flow into the subretinal space overwhelm the capacity of the RPE to pump fluid from this potential space. Rotary eye movements coupled with the viscosity and inertial quality of the subretinal fluid can cause further extension of the retinal detachment (Fig. 6.39.6).

## Conditions Predisposing an Eye to Retinal Detachment

Although uncommon in the general population, RRDs occur with higher frequency in a variety of conditions associated with early PVDs: pseudo-phakia, aphakia, high myopia ( $>-6.00$  diopters [D]), and hereditary collagen–vascular disorders, such as Stickler’s and Marfan’s syndromes. Other causes of RRDs, not necessarily related to premature PVD development, include proliferative retinopathy (breaks caused secondarily by

**Fig. 6.39.4 Vitreoretinal Traction Caused by Eye Movements.** When the eye rotates, the inertia of the vitreous gel causes it to lag behind the eye movement, which effectively causes vitreoretinal traction (“drag”) in the opposite direction and the production of a retinal tear, with a small amount of associated subretinal fluid. (Courtesy Charles P. Wilkinson.)

**Fig. 6.39.6 Extension of Subretinal Fluid Associated With Eye Movements.** In addition to exacerbating vitreoretinal traction, rotary eye movements have an inertia effect on subretinal fluid that causes it to dissect further between the retina and pigment epithelium. (Courtesy Charles P. Wilkinson.)

**Fig. 6.39.5 Extension of Retinal Detachment Associated With Eye Movements.** Rotary eye movement causes movement of the vitreous gel, which increases traction on the retinal break. In addition, liquid currents dissect beneath the edge of the retinal tear and push against the vitreous gel adjacent to the tear. All three factors promote extension of the retinal detachment. (Courtesy Charles P. Wilkinson.)

contractile tractional membranes), trauma, and viral retinitis associated with immunodeficiency.

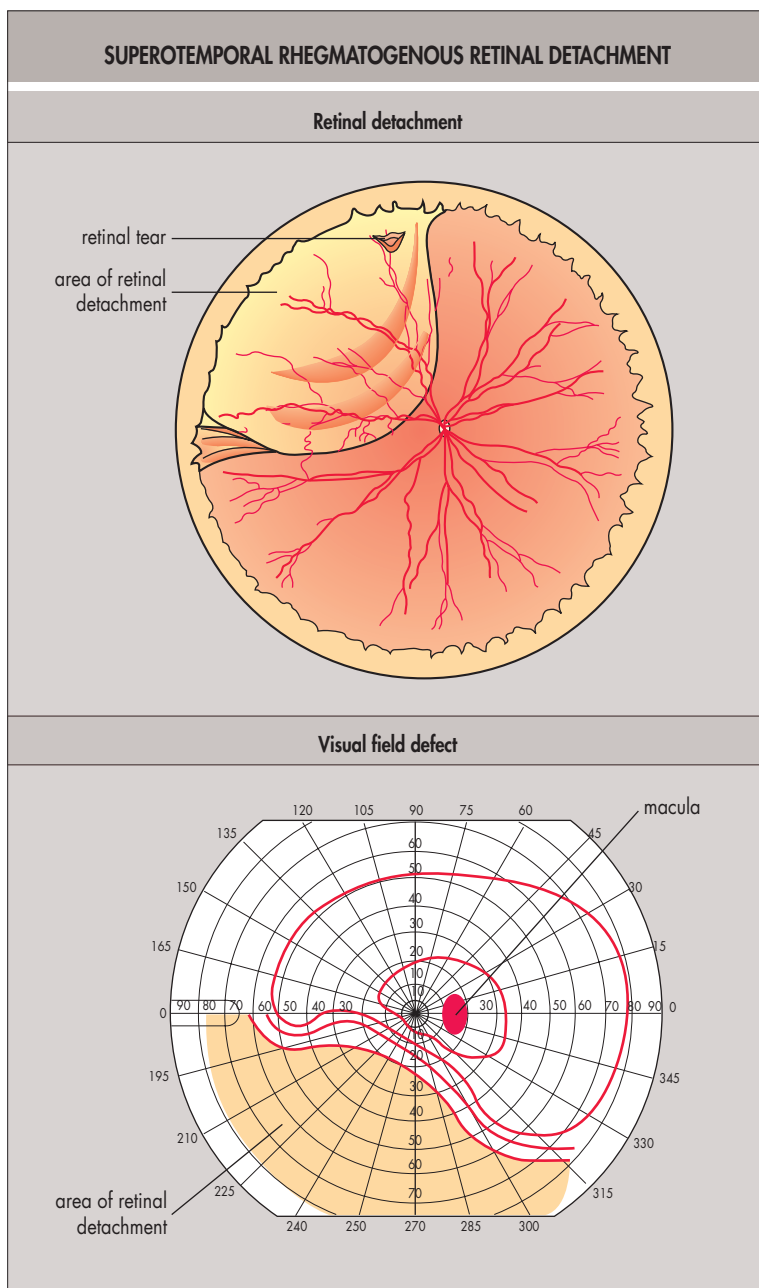

Up to 40% of eyes with retinal detachment have had prior cataract surgery, even though risk of RRD after cataract extraction is approximately 0.7%.<sup>6</sup> Among this population with pseudo-phakia, patients who are male, of younger age, and experience intraoperative posterior capsular rupture carry a higher risk of RRD.<sup>7</sup> Crystalline lens extraction is believed to increase the risk of retinal detachment as a result of early induction of PVD. Although the status of the posterior capsule has been considered a factor in RRD development, especially with regard to neodymium:yttrium–aluminum–garnet (Nd:YAG) laser capsulotomy, various studies have reported mixed conclusions.<sup>8,9</sup>

Risk factors for retinal detachment are not mutually exclusive and may be additive. For example, prior cataract extraction and nonsurgical trauma are more likely to be complicated by retinal detachment in myopic eyes. Pathological vitreoretinal changes often occur bilaterally—patients who have a retinal detachment in one eye have a significantly increased risk of retinal detachment in the fellow eye, provided that additional acquired risk factors are comparable. There is conflicting evidence regarding an association between the use of oral fluoroquinolones, an antibiotic linked to tendon rupture secondary to collagen degeneration, and RRD development.<sup>10-12</sup>

## OCULAR MANIFESTATIONS

The early symptoms of RRD remain indistinguishable from acute PVD: sudden appearance of floaters, frequently associated with fleeting photopias (flashes). These symptoms are more noticeable in the dark and following rotary eye movements. Subclinical RRDs can be asymptomatic and are associated with limited dissection of subretinal fluid (<2 disc diameters from the break). Rarely, but especially in young patients with myopia, slowly progressive asymptomatic retinal detachments develop without PVD. This most commonly occurs temporally and inferiorly and secondary to atrophic holes in lattice degeneration.<sup>9</sup>

Because of the persistent attachment of vitreous at the vitreous base after PVD, most retinal breaks occur anteriorly. The accumulation of subretinal fluid produces relative scotomata, which, when the detachment progresses posterior to the equator, can be symptomatic with loss of

**Fig. 6.39.7 Superotemporal Rhegmatogenous Retinal Detachment (RRD).** The neural retina is elevated in the area of detachment and the macula remains uninvolved. Visual field defect associated with retinal detachment shows that peripheral vision is lost inferonasally, corresponding to the area of detachment. The visual defect is an inverted image of the retinal detachment. (Courtesy Charles P. Wilkinson.)

peripheral vision, producing the sensation of a “curtain falling” over the visual field (Fig. 6.39.7). Central visual acuity is lost when subretinal fluid passes beneath the macula. Frequently, patients do not notice any symptoms until the macula becomes involved.

The location of the RRD generally predicts the most likely locations of the retinal break(s).<sup>13</sup> Retinal breaks are usually present superiorly within the area of detachment (Fig. 6.39.8). Retinal detachments that involve the inferior quadrants tend to follow the same rules, but the progression of the detachment is often much slower, and symmetrical spread of subretinal fluid may occur on both sides of the break. Therefore, detachments that involve one or both inferior quadrants may have a break near a superior margin of the detachment or in the meridian that bisects the area of detachment (Fig. 6.39.9).

## DIAGNOSIS

The majority of causative retinal breaks associated with RRD are found by binocular stereoscopic examination of the entire retina, with scleral indentation of the peripheral retina. Areas of retinal detachment are recognized by elevation of the neural retina from the RPE and loss of pigment epithelial and choroidal detail beneath the elevated retina (Fig. 6.39.10). In

**Fig. 6.39.8 Location of the Retinal Break.** Retinal detachments that involve both quadrants on the same side of the vertical meridian are usually caused by a retinal break within 1–1.5 clock hours of the superior margin of the detachment. (Courtesy Charles P. Wilkinson.)

**Fig. 6.39.9 Location of the Retinal Break.** Retinal detachments that involve both lower quadrants but extend farther superiorly on one side are usually caused by a retinal break within 1–1.5 clock hours of the superior margin of the retinal detachment or by a break in a meridian that bisects the margins of the retinal detachment. (Courtesy Charles P. Wilkinson.)

pseudo-phakic RRD, all breaks may not be visible because of very small tears; and adjunctive treatment maneuvers may be employed at the time of RRD repair (e.g., 360° circumferential laser retinopexy). In eyes with opaque media, the presence of a retinal detachment is usually determined ultrasonographically; the location and identification of the causative retinal

**Fig. 6.39.10 Rhegmatogenous Retinal Detachment (RRD).** There is full-thickness retinal break in the superior temporal retina associated with RRD. The subretinal fluid makes visualization of the pigment epithelium and choroid relatively difficult.

#### BOX 6.39.1 Differential Diagnosis of Rhegmatogenous Retinal Detachment

##### Traction Retinal Detachment

- Proliferative diabetic and other retinopathies
- After penetrating trauma

##### Exudative Retinal Detachment

- Inflammatory disorders
- Choroidal neoplasms
- Retinal vascular tumors and other disorders

##### Retinoschisis

- Age-related
- Congenital gender-linked

##### Elevated Choroidal Lesions

- Choroidal detachments
- Choroidal tumors

##### Vitreous Hemorrhage

breaks are based on the configuration of the detachment as well as on the patient's history and associated findings.

## DIFFERENTIAL DIAGNOSIS

RRDs must be distinguished from serous or tractional retinal detachments and retinoschisis (Box 6.39.1). Choroidal lesions that elevate the overlying retina and intravitreal pathology that simulates an elevated retina may also be confused with retinal detachment.

The distinction between different types of retinal detachment can be difficult in eyes with small or undetectable retinal breaks, opaque media, and features associated with intraocular proliferation or exudation. In some cases, a combined mechanism that involves both rhegmatogenous and traction components, or an exudative component may be a clue to the pathogenesis of the detachment. This is particularly common in eyes with proliferative diabetic retinopathy and retinal detachment. Traction detachments usually have a concave surface, and the shape, location, and extent of the detachment can be accounted for by the evident vitreous traction (Fig. 6.39.11). Exudative detachments from a variety of causes are characterized by shifting subretinal fluid, which assumes a dependent position beneath the retina. In most cases, the fluid is located inferiorly and its cause within or beneath the retina may be apparent (Fig. 6.39.12) or quite subtle. Retinoschisis tends to have a smooth, noncorrugated, bullous appearance that may be associated with inner and outer retinal holes.

**Fig. 6.39.11 Traction Retinal Detachment.** The central and temporal areas of retinal elevation are caused by areas of visible vitreoretinal traction associated with proliferative vitreoretinopathy. The traction of the epiretinal membranes has caused a full thickness break (rhegmatogenous component) at the temporal periphery.

**Fig. 6.39.12 Exudative Retinal Detachment.** The small amounts of subretinal fluid (note the retinal striae) are due to leakage from an inflammatory process that involves the choroid and retinal pigment epithelium. (Courtesy Charles P. Wilkinson.)

Although typically observed, retinoschisis with an outer retinal hole may lead to a true retinal detachment that requires treatment. In chronic cases, a demarcation pigment line suggests the presence of fluid egress via an outer wall hole into the subretinal space, creating a detachment. Wide-field infrared imaging can aid in differentiating retinoschisis, RRDs, and combined retinoschisis/RRDs (Fig. 6.39.13).<sup>14</sup>

## PATHOLOGY

Retinal breaks, liquefaction and collapse of the vitreous gel, and visible vitreoretinal adhesions have been well documented histopathologically. Nutrition of the outer retina is lost during retinal detachment, so the first visible pathological retinal changes occur in the outer segments of the photoreceptors.<sup>15</sup> Optical coherence tomography (OCT) images of the macula in patients with macula-off RRDs confirm the aforementioned retinal changes in vivo with loss of the photoreceptor inner and outer segment (IS/OS) junction.<sup>16</sup> Long-standing retinal detachments are associated with further atrophy of the photoreceptor layer, intraretinal cystic degeneration, pre- and subretinal cysts, and membrane formation. Photoreceptor outer segments from RRD have been identified in the aqueous fluid and irido-corneal angle and can lead to glaucoma.<sup>17</sup>

Successfully repaired retinal detachments show a variety of histopathological abnormalities. There is a high incidence of epiretinal membrane (ERM) formation.<sup>18,19</sup> Cystoid macular edema is common as well, along with significant photoreceptor atrophy in many eyes.

**Fig. 6.39.13 Wide-Field Infrared Imaging of Retinoschisis Versus Rhegmatogenous Retinal Detachment (RRD).** (A) Retinoschisis appears light and translucent with prominent vasculature. (B) RRDs appear dark and opaque. (C) Combined retinoschisis/RRDs exhibit mixed reflectivity patterns.

### BOX 6.39.2 Options for the Management of Primary Retinal Detachment

- Observation (very rarely employed)
- Laser demarcation
- Permanent scleral buckling
  - Encircling with/without drainage
  - Segmental with/without drainage
- Temporary scleral buckling
  - Lincoff balloon
  - Absorbable buckling materials
- Pneumatic retinopexy
  - Routine
  - With drainage of subretinal fluid or intravitreal liquid
- Primary vitrectomy
- Combinations of the above techniques

## TREATMENT

The aim of retinal detachment therapy is to counter the factors and forces that cause retinal detachment and to re-establish the physiological conditions that normally maintain contact between the neural retina and pigment epithelium. The main goal of surgery (i.e., to close each retinal break) is usually sufficient to reattach the retina. Long-term closure of retinal breaks may also require permanent reduction or elimination of vitreoretinal traction, accompanied by maneuvers designed to offset the harmful effects of fluid currents in the vitreous cavity.

At present, many retinal surgeons continue to use scleral buckling techniques and the creation of a chorioretinal adhesion around each break to eliminate and counteract vitreoretinal traction, especially in younger patients without PVD (see Chapter 6.11). Vitrectomy techniques have emerged as the predominant approach in repair of pseudo-phakic RRD (see Chapter 6.12). A prospective clinical trial has demonstrated some benefit to visual acuity provided by scleral buckling versus vitrectomy in phakic RRDs, but vitrectomy has been shown to result in better anatomical success in pseudo-phakic RRDs.<sup>20</sup> As a result of advances in instrumentation, vitrectomy, with or without concurrent scleral buckling, continues to gain popularity. The use of primary scleral buckling (i.e., without concurrent vitrectomy) continues to decline because of lack of training in many vitreoretinal training fellowships. This approach, however, remains a useful and important procedure primarily in patients with phakia and a formed vitreous. Although earlier studies have shown a significant rate of strabismus and extrusion (e.g., as high as 24.4%), newer analyses have shown clear improvements in scleral buckling–associated morbidity.<sup>21, 22</sup> Pneumatic retinopexy is a third technique that is frequently employed in selected cases. Contemporary options in the management of RRD are listed in Box 6.39.2.

## COURSE AND OUTCOME

RRD was essentially untreatable until approximately 80 years ago. Surgical success rates have improved profoundly and are equally high and comparable for vitrectomy, scleral buckling, and a combined scleral buckling/vitrectomy.<sup>23</sup> A recent meta-analysis reported that combining scleral buckling and vitrectomy increases the rate of primary reattachment, but the final success rate for both procedures individually was equally high.<sup>24</sup> Pneumatic retinopexy can have a high surgical success rate, up to 82% with appropriate case selection and proper adherence to postoperative care by patients.<sup>25</sup> Approximately 95% of all retinal detachments can be successfully repaired (i.e., the retina is returned to its normal anatomical position with no residual subretinal fluid).

The three most common reasons for failure of retinal detachment surgery are as follows:

- Failure to identify and/or close all retinal breaks.
- New retinal breaks.
- Proliferative vitreoretinopathy.

The choice of the initial procedure determined the subsequent rate for secondary intervention, including silicone oil insertion and lensectomy. Recurrent retinal detachment that occurred after a primary scleral buckling procedure required, on average, one subsequent procedure, whereas eyes initially repaired with primary vitrectomy or scleral buckling combined with vitrectomy were associated with 1.5 subsequent procedures. The primary vitrectomy and combined scleral buckling–vitrectomy groups were also associated with lensectomy and silicone oil insertion.

Unfortunately, postoperative best-corrected visual acuity (BCVA) does not always correlate with the high rate of anatomical success of surgery. Postoperative BCVA is most dependent on the extent of damage to the macula caused by retinal detachment. If the macula is detached by subretinal fluid, some degree of permanent damage to vision usually occurs in spite of surgical reattachment. In eyes with a macula-on detachment, 73% can be expected to have postoperative  $\geq 20/40$  vision  $\geq 2$  months after surgery.<sup>26</sup> In eyes with a macula-off detachment, postoperative mean visual acuities depend on the duration of macular detachment (DMD), with acuity of  $\geq 20/40$  in 71% of eyes with DMD of  $\leq 10$  days, 27% of eyes with a DMD of 11 days to 6 weeks, and 14% of eyes with a DMD of  $> 6$  weeks.<sup>27</sup> OCT images of the macula in patients with macula-off RRDs confirm loss of the photoreceptor IS/OS junction compared with those in patients with macula-on detachments. In macula-off detachments, decrease in postoperative visual acuity correlates to loss of signal from the IS/OS and external limiting membrane.<sup>16</sup> Additional studies have suggested other metrics from OCT images, such as the integrity of the intermediate line and outer nuclear layer and presence of a foveal bulge, an increase in combine RPE–IS/OS junction thickness, may be important predictors of postoperative visual acuity after successful reattachment of the retina.<sup>28–30</sup>

Disappointing postoperative vision may also result from nonexclusive complications caused by the following:

- Subsequent reattachment surgery.
- Progressive ischemic or infectious retinal damage.
- Persistent subretinal fluid despite closure of all retinal breaks.<sup>31, 32</sup>

See clip:  
6.39.1

The most common of such entities, other than macular damage from the detachment, are cystoid macular edema (5%–10%) and postoperative ERM. Scleral buckling has been associated with a 3%–8.5% rate of postoperative ERM formation.<sup>33,34</sup> Postoperative ERM formation following vitrectomy has been estimated at 12.8%–34.3%; secondary surgery for subsequent ERM removal in these series ranged from 4.3%–9.4%.<sup>19,35</sup> The higher rate associated with vitrectomy may have resulted from enhanced intraocular liberation of membrane-forming elements, such as RPE, during retinotomy creation. Peeling the internal limiting membrane (ILM) during primary RRD detachment repair reduces the formation of postoperative ERM.<sup>19,36,37</sup> Previously, in retinal detachment secondary to proliferative vitreoretinopathy, a 27.3% rate of postoperative ERM was reduced to 0% after ILM peeling during primary RRD repair.<sup>19,38</sup> The technique of ILM peeling during primary RRD repair may appear challenging, but with the use of adjuncts, such as triamcinolone acetonide, fluid–fluid exchange through an existing break or a retinotomy site, and proper instrumentation, ILM can be stripped consistently in most cases (Video 6.39.1). Perfluorocarbon liquid can also be used to stabilize the macula to achieve safer ILM peeling.

# Serous Detachments of the Neural Retina

6.40

Benjamin J. Thomas, Thomas A. Albini

**Definition:** An elevation of the neural retina caused by the accumulation of subretinal fluid in the absence of a retinal break or significant preretinal traction.

## Key Features

- Subretinal fluid that shifts with postural changes.
- Lack of rhegmatogenous or tractional component.
- Occurs secondary to local ocular or systemic etiology.

## Associated Features

- Involves a breakdown in the blood–retina barrier.
- Absence of retinal corrugations or fixed folds in the detached retina.
- Clear or lipid-rich exudate within the subretinal fluid.
- Presence of local ocular pathology or systemic disease associated with serous detachments.

## INTRODUCTION

Serous detachment of the neural retina, like its rhegmatogenous and tractional counterparts, represents a breakdown of the normal anatomical arrangement of the retina and its supporting tissues, causing accumulation of fluid between the neural retina and the retinal pigment epithelium (RPE). However, rather than resulting from a retinal break or traction on the retina, serous detachments stem from more subtle disruptions of the forces underlying the normal apposition of the retina, RPE, Bruch's membrane, and choroid.

Because any disruption can lead to accumulation of fluid in the subretinal space, the differential diagnosis for serous detachments is broad and heterogeneous, encompassing etiologies from choroidal neoplasms to congenital structural defects. Nonetheless, there are certain features that define all serous retinal detachments. These include accumulation of serous fluid (with or without associated exudates) in the subretinal space without an associated retinal tear or tractional membrane, a characteristic shifting of this fluid to a dependent position with postural changes, a smooth dome-shaped appearance of the detached retina that lacks corrugations or fixed folds, and the presence of associated systemic or local pathology.

## PATHOPHYSIOLOGY

Fully appreciating the means whereby serous detachments occur requires an understanding of the forces necessary to maintain retinal attachment. Consequent to the embryological development of the retina and the RPE, the adhesion of these two layers depends on the interdigitating processes of their apical surfaces and the surrounding extracellular matrix.<sup>1</sup> These adhesive forces are easily overcome if proper movement of fluid from the vitreous to the external layers of the posterior eye is disrupted. This movement begins from the vitreous to the RPE, where the resistance provided by an intact retina helps “push” the retina down onto the choroid and limits the amount of fluid being presented in the subretinal space (see Chapter 6.1). Next, the RPE, through a system of adenosine triphosphate-driven pumps, moves solute and fluid from the subretinal space into

the underlying choroid.<sup>2</sup> Reflux of fluid is minimized by tight junctions between RPE cells. The choroid, which is both highly vascular and highly permeable, employs both hydrostatic and osmotic forces to “pull” fluid through the RPE and out through the venous drainage, effectively creating a vacuum to pull the retina into apposition with the RPE. Finally, any fluid that cannot be removed by way of the choroid escapes through the sclera, completing internal to external fluidic movement.<sup>1</sup>

Serous detachments occur when this fluid movement through the choroid is misdirected or inhibited, as when choroidal neoplasms disrupt choroidal fluidics, or changes in the scleral thickness, as can occur in nanophthalmos, decrease fluid outflow. Further, any disruption of the RPE, or its active transport, will lead to fluid accumulation in the subretinal space. Taken together, these three mechanisms—alterations in choroidal flow, poor scleral outflow, and breakdown of the RPE—serve as convenient headings for the grouping of the various etiologies that lead to serous retinal detachments and will be treated in this order.

## ALTERATIONS IN CHOROIDAL FLOW

### Idiopathic Central Serous Chorioretinopathy

One of the more commonly seen etiologies of serous retinal detachment is idiopathic central serous chorioretinopathy (ICSC), which often affects young, otherwise healthy individuals in the third to fourth decade of life. A significant male predominance exists, and there is likely an association with both type A personalities and patients using exogenous corticosteroids. Pregnancy also carries an increased risk of ICSC (Fig. 6.40.1).<sup>3</sup> These patients experience decreased vision, metamorphopsia, and decreased color vision, and although spontaneous return of vision is common, long-term dysphotopsias are a frequent complaint.

In ICSC, fluorescein angiography (FA) reveals defects in the integrity of the RPE, most commonly as an “expansile dot” of leakage or, classically, a “smokestack” pattern of focal leakage. Late pooling within the areas of retinal detachment is also seen. Additionally, two other forms of ICSC have been reported: a chronic form, also known as *diffuse retinal pigment epitheliopathy*, and a more bullous form, which often manifests in the inferior retina.<sup>1</sup>

Debate continues as to whether ICSC is primarily a defect of the RPE or the choroid. The primary finding on FA is a focal loss of integrity of the RPE; however, more recent studies using indocyanine green angiography (ICGA) have shown that underlying these focal RPE defects are areas of choroidal hyperpermeability, seen in the middle phases of angiography. Observation of hyperpermeable choroid, interspersed with areas of delayed filling, has led some researchers to propose a pathological mechanism of primary choroidal vasculopathy or thrombosis, perhaps leading to focal RPE defects and subsequent overlying retinal detachment. This theory implicates a thrombotic mechanism leading to focal disruption or necrosis of the RPE and may represent a pathological mechanism similar to that which produces serous retinal detachments in some diseases, such as immunoglobulin A nephropathy, type II glomerulonephritis, and cryoglobulinemia.<sup>2</sup>

Treatment has traditionally been observation, as most cases resolve spontaneously. However, in atypical or recurrent cases, or in rare cases with associated choroidal neovascularization, one can consider focal laser photocoagulation or anti-vascular endothelial growth factor (VEGF). In addition, reduced fluence photodynamic therapy (PDT) with verteporfin has been employed, most commonly for the chronic form of ICSC.<sup>3</sup> Finally, oral agents that block aldosterone, primarily spironolactone

**Fig. 6.40.1** A 21-Year-Old Woman in the Third Trimester of Pregnancy With Acute Idiopathic Central Serous Chorioretinopathy in the Left Eye. (A) Fundus photo shows area of neurosensory detachment superior to and involving fovea. (B) Optical coherence tomography (OCT) confirms subfoveal fluid.

and eplerenone, have demonstrated reductions in subretinal fluid and improved visual acuity.

## Tumors of the Choroid and Retina

Choroidal melanomas and nevi, hemangiomas, metastatic choroidal lesions, and even retinoblastoma, can cause serous retinal detachments. Aberrant vascular patterns with increased permeability (mediated, perhaps, by VEGF), or physical disruption of the net flow from vitreous to choroid, leads to breakdown in the normal internal to external fluid movement and subsequent serous detachment.<sup>1</sup> Additionally, rapid growth of a lesion with outstripping of its blood supply and ischemia can lead to overlying RPE damage and retinal detachment and may serve as a marker of malignant transformation, especially in the setting of choroidal nevi and melanoma. However, benign lesions, such as nevi and hemangiomas, can also cause serous retinal detachments, seen both clinically and by optical coherence tomography (OCT).<sup>4</sup>

Choroidal hemangiomas occur in two forms: the diffuse hemangioma associated with Sturge-Weber disease, described as having a “tomato catsup” appearance, and a clinically isolated form usually having a single subretinal lesion that is well-circumscribed and often located near the optic nerve or macula. These tumors are well vascularized, with contributions from both ciliary and choroidal vessels, and tend to induce changes in the overlying RPE ranging from atrophy to hypertrophy. Serous retinal detachments are a common feature.<sup>5</sup>

Choroidal melanomas are often dome-shaped subretinal lesions that can be variably pigmented, although “mushroom-shaped” (if the tumor violates Bruch’s membrane, which forms a “collar” between the sub-RPE “stalk” and the subretinal “cap”) and diffuse presentations are also possible. On FA, these tumors appear hyperfluorescent because of their dilated, highly permeable vascular networks, often with a speckled pattern at the margins. In addition, they may also show a distinct “double circulation” pattern, with midphase hyperfluorescence highlighting the permeable vasculature and late hyperfluorescence the fluid extravasated within the tumor substance.<sup>6</sup> These disrupted vascular patterns seen within melanomas lead to the fluid disruptions causing serous detachments.<sup>1</sup>

This is likely the same mechanism whereby serous retinal detachments are caused in metastatic lesions of the choroid. Choroidal metastases most commonly arise from breast adenocarcinoma in women (Fig. 6.40.2) and from lung adenocarcinoma in men, although primary lesions are not determined in a number of choroidal lesions.<sup>7</sup> Metastases often show late hyperfluorescence on FA, often with pooling of dye into overlying serous detachments.<sup>1</sup> Treatment is aimed at the underlying primary malignancy and should be coordinated with an oncologist.

Rapidly growing retinoblastomas, often exophytic in growth, are also highly vascularized tumors and can be seen to produce large serous detachments of overlying and surrounding retina. As the most common primary intraocular malignancy in children, retinoblastomas often manifest as a chalky white tumor with extensive calcification. Treatment traditionally consisted of enucleation, but significant advances in globe- and

**Fig. 6.40.2** A 56-Year-Old Woman With a History of Breast Cancer Presents With Serous Retinal Detachment and Choroidal Metastasis. (A) Fundus photo of right eye shows serous retinal detachment. Bernadete Ayres, Echography Department, Bascom Palmer Eye Institute.)

vision-sparing therapy have been made through the use of localized chemotherapy.<sup>8</sup>

### Systemic Disease With Disrupted Choroidal Blood Flow

Other, more systemic processes which disrupt normal choroidal flow and lead to overlying serous retinal detachments include malignant hypertension, disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, renal failure, and pre-eclampsia. Although diverse in pathophysiology and presentation, each of these entities produces a thrombotic, occlusive state that causes focal areas of choroidal and retinal ischemia.<sup>2</sup> Signs of retinal ischemia, such as cotton-wool spots, are common in each disease, and can be seen in association with optic nerve swelling and peripapillary leakage, as well as placoid RPE and choroidal lesions. These areas of atrophy can resolve to form the Elschnig's spots and Siegrist's streaks associated with malignant hypertension and pre-eclampsia. FA reveals areas of patchy hypofluorescence, demonstrating focal areas of occlusion and disrupted choroidal blood flow, and these choroidal lesions are often associated with overlying serous retinal detachments. Treatment is directed at the underlying pathology.<sup>1</sup>

### Vasculitis and Autoimmune Disease

In addition to the systemic conditions above, there are several vasculitic syndromes that cause intraocular inflammation and serous retinal detachments, including systemic lupus erythematosus (SLE), Wegener's granulomatosis, polyarteritis nodosa, relapsing polychondritis, dermatomyositis, and Goodpasture's disease. Each produces vascular leakage and/or acute occlusion of the choriocapillaris, or precapillary choroidal arterioles, resulting in necrosis of the overlying RPE and retinal detachment by the mechanism described above.<sup>2</sup>

SLE—a chronic, systemic, immunologically mediated disease of unknown etiology—in addition to its protean effects throughout the body, is able to affect almost every ocular structure. One more common ocular manifestation is a retinopathy consisting of cotton-wool spots, retinal arteriitis and vascular occlusion, and secondary retinal neovascularization and vitreous hemorrhage. Although rare, associated choroidopathy with serous retinal detachment can complicate this retinopathy and is usually associated with severe SLE, secondary hypertension, and renal involvement. Diagnosis of SLE, and other inflammatory diseases, is best done in conjunction with a rheumatologist, and treatment is directed at systemic control.<sup>9</sup>

### POOR SCLERAL OUTFLOW

#### Nanophthalmos and Uveal Effusion Syndrome

Given the role of normal scleral outflow in removing excess fluid from the choroidal interstitium, any impedance of this outflow can result in disruption of the normal flow of fluid from out of the subretinal space and subsequent serous detachment of the neural retina. Nanophthalmos, although rare, illustrates this point. Nanophthalmos is an uncommon disorder of ocular development characterized by short axial length, high hyperopia, high lens-eye volume ratio, and a predisposition to angle closure, which shows variable genetic inheritance patterns. Patients universally have abnormally thickened sclera and can exhibit serous retinal detachments in the absence of other inciting factors.<sup>10</sup>

This association helped classify nanophthalmos as a distinct class of uveal effusion syndrome (Fig. 6.40.3), along with eyes of normal axial length with abnormal scleral collagen and eyes of normal axial length and normal scleral collagen. In addition to serous detachments, these patients exhibit dilated conjunctival vessels, shallow anterior chambers, ciliochoroidal effusions, and increased risk of glaucoma. On FA, these patients often demonstrate a diffuse “leopard spot” pattern that notably lacks focal points of leakage, and ICGA shows diffuse hyperfluorescence. Although the exact mechanism of impedance is uncertain, decreased fluid movement through the sclera is the cause of fluid accumulation in the subretinal space, and treatments improving scleral outflow—such as the creation of scleral “windows”—successfully treat the detachments.<sup>10</sup>

### Posterior Scleritis

Other mechanisms of decreasing scleral outflow similarly lead to serous retinal detachment. Posterior scleral inflammation and edema, as seen in posterior scleritis and orbital cellulitis, have been reported with serous detachments.

Posterior scleritis presents with severe retrobulbar pain, decreased vision, and posterior segment inflammation. Ultrasonography is useful for diagnosis and reveals diffusely thickened posterior sclera.<sup>1</sup> Treatment, similar to other forms of scleritis, consists of high-dose corticosteroids. Orbital cellulitis, although able to cause posterior scleral inflammation and decreased fluid outflow, is less commonly associated with posterior retinal changes and only rarely exhibits serous retinal detachment.<sup>11</sup> Other infectious etiologies affecting the posterior globe, such as Lyme disease and cat scratch disease, can exhibit small peripapillary serous detachments. Treatment consists of antibiotic therapy tailored to the particular infectious agent.

### BREAKDOWN OF THE RPE AND RETINA

#### Vogt–Koyanagi–Harada Disease, Sympathetic Ophthalmia, and Sarcoidosis

A more diverse group of pathological entities—inflammatory, infectious, degenerative, and vascular—can cause focal disruption of the RPE and

**Fig. 6.40.3** A 60-Year-Old Man With Chronic Uveal Effusion Syndrome and Hyperopia. (A) Fundus photo shows extensive inferior serous retinal detachment of left eye. (B) Optical coherence tomography (OCT) of subretinal fluid throughout macula with chronic degenerative cysts and hyperreflective lesions in subretinal space and outer retina.

retina, overwhelming the natural outflow of fluid into the choroid and causing accumulation of fluid in the subretinal space.

Vogt-Koyanagi-Harada disease (VKH) is an inflammatory disease found more commonly in Asian and Native American populations, defined principally by intraocular inflammation (panuveitis) associated with exudative retinal detachments (Fig. 6.40.4). Vision loss is nearly universal, with associated headache, meningismus, poliosis, vitiligo, and hearing loss. The pathological mechanism is an autoimmune response to melanin-containing tissues, which explains the predilection for the RPE and the highly pigmented choroid.<sup>12</sup>

In patients with VKH disease, FA reveals patchy filling of the choroid, followed by multiple pinpoints of hyperfluorescence and eventual pooling of dye in areas of exudative detachment. ICGA reveals diffuse hyperpermeability of the choroidal vasculature, in contrast to the lobular pattern seen in ICSC, indicating diffuse inflammatory damage present within VKH

disease.<sup>1</sup> RPE breakdown, formation of sub-RPE Dalen-Fuchs nodules, and choroidal inflammation involving the choriocapillaris are key features of this damage, which leads to subretinal fluid accumulation and exudative retinal detachment. Sympathetic ophthalmia (SO), characterized by an immune reaction to ocular tissue in the wake of a penetrating ocular injury, is rarer, but can present a similar pathological picture.<sup>13</sup>

Another inflammatory condition, sarcoidosis, can also present with associated serous retinal detachment. Sarcoidosis is a systemic granulomatous disease of unknown etiology that affects the eye in approximately 25% of patients. Association with RPE detachments has been described in patients with sarcoidosis, presumably from inflammation leading to RPE breakdown and subretinal fluid accumulation.<sup>14</sup>

## Infectious Diseases

Various infections can damage the retina, RPE, and choroid, leading to RPE breakdown and serous retinal detachment. Toxoplasmosis, a protozoal infection and the most common cause of posterior uveitis, causes a necrotizing chorioretinopathy that leads to characteristic scarring. Almost a quarter of patients with *Toxoplasma* retinochoroiditis in one series demonstrated serous detachment. These detachments were, in the majority of cases, associated with areas of retinal and vascular damage, as well as likely RPE breakdown, although some patients showed associated areas of choroidal ischemia, suggesting a mixed mechanism for serous retinal detachment.<sup>15</sup> Treatment is aimed at the underlying infectious process and leads to resolution of the associated retinal detachment. Syphilis and cytomegalovirus have also been reported in association with serous retinal detachments.<sup>2</sup> Additionally, Lyme disease (caused by *Borrelia burgdorferi*), tuberculosis, histoplasmosis, coccidiomycosis, and cryptococcosis have all been associated with serous retinal detachment, and cat scratch disease (caused by *Bartonella henselae*) and other neuroretinitides can cause peripapillary serous detachments.<sup>16</sup>

## Retinal Vascular Diseases

Other vascular pathologies, each involving leakage of abnormal retinal vessels or breakdown of normal ones, can cause serous detachments. Congenital vascular abnormalities with associated retinal detachment include those seen in Coats' disease, familial exudative vitreoretinopathy (FEVR), and retinal angiomas. Coats' disease, a rare disease of unknown inheritance with a 3:1 male predominance, presents at an early age and is classically thought to be a unilateral disease. The characteristic presentation is capillary nonperfusion and telangiectasias, with massive exudation of fluid and cholesterol.<sup>17</sup> FA demonstrates "light bulb" aneurysms of the congenitally weakened vessels, and arterioles, capillaries, and venules are all affected. The leakage and exudation leads to serous retinal detachment, compounding the vascular damage and eliciting a progressive cycle of worsening detachment. Treatment usually involves laser photocoagulation, although recent studies have evaluated the use of anti-VEGF therapy.<sup>1</sup>

Congenital retinal vascular abnormalities causing pathologically increased flow and focal leakage are also present in FEVR and retinal angiomas. Capillary hemangiomas of the retina can be seen in isolation (von Hippel's disease), or in association with systemic tumors, such as central nervous system hemangioblastomas and renal cell carcinoma (von Hippel-Lindau disease).<sup>1</sup> Again, treatment of retinal lesions is commonly laser photocoagulation, although PDT has been used with some success. Suspected von Hippel-Lindau disease requires further imaging to rule out associated neoplasms.

Acquired vascular damage can also lead to serous retinal detachment, as has been reported in association with retinal vein occlusions, diabetic macular edema, retinal macroaneurysms, and exudative age-related macular degeneration (AMD).

## MISCELLANEOUS

- Multiple myeloma/immune gammopathies/paraproteinemias.
- Postoperative (e.g., retinal detachment repair, phacoemulsification).
- Medication-related: interferon, ribavirin, mitogen-activated protein kinase kinase inhibitors, phosphodiesterase inhibitors, ipilimumab, dabrafenib, trametinib, deferoxamine.
- Congenital optic nerve anomalies (optic pit, coloboma, morning glory).
- Myopia-related: dome-shaped maculopathy, posterior staphyloma, tilted disc syndrome.
- Bilateral diffuse uveal melanocytic proliferation (BDUMP).

**Fig. 6.40.4 A 45-Year-Old With Man With Acute Vogt-Koyanagi-Harada (VKH) Disease.** (A) Fundus photograph of right eye with minimal vitritis and shallow serous retinal detachment in macula. (B) Optical coherence tomography (OCT) shows hyperreflective fibrinous structures lining retinal pigment epithelium (RPE) and photoreceptor layer in areas of neurosensory detachment, including formation of a fibrinous membrane extending through subretinal space. (C) B-scan of another patient with VKH disease shows diffuse thickening of retinochoroidal layer, shallow serous retinal detachment, and posterior vitreous detachment with inflammatory debris in vitreous.

## DIAGNOSTIC AND ANCILLARY TESTING

The presence of a serous retinal detachment is most readily established by clinical examination using indirect ophthalmoscopy, unless precluded by hazy ocular media. Initial examination should include careful evaluation for retinal breaks or tractional membranes. Observation of fluid shifting with changes in head position, as well as the absence of retinal corrugations or tractional membranes, is an important diagnostic clue. Complete

ocular examination for structural abnormalities, inflammatory manifestations, tumors, or vascular disease helps narrow the diagnosis, and a thorough review of systems is critical.

Ancillary imaging serves two purposes: first, evaluation in the setting of hazy ocular media or retrobulbar pathology, as with B-scan ultrasonography and computed tomography/magnetic resonance imaging (CT/MRI); second, demonstration of various pathological patterns, assisting in diagnosis. Additionally, blood testing (as with infectious and autoimmune

**Fig. 6.40.5** A 43-Year-Old Woman With Posterior Scleritis. Transverse B-scan in the peripapillary region shows diffuse thickening of the retinochoroidal layer and sclera. The edematous distention of the sub-Tenon's space produces the "T" sign (arrows). (Courtesy M. Bernadete Ayres, Echography Department, Bascom Palmer Eye Institute.)

etiologies) and cerebrospinal fluid sampling (as with VKH disease) can be useful.

### Diagnostic Ultrasonography

B-scan ultrasonography, which assists in the examination of patients with hazy ocular media, can also provide important diagnostic information. Serous retinal detachments usually appear as smooth, dome-shaped collections of subretinal fluid. Fluid shifting can also be appreciated by ultrasonography. Associated macrostructural pathology, such as choroidal tumors or thickening of the posterior sclera (e.g., the "T" sign in posterior scleritis; Fig. 6.40.5), can be seen. Diffuse choroidal thickening can be seen in both VKH disease and SO.

### Optical Coherence Tomography

OCT provides in vivo, cross-sectional images of the retina with resolution sufficient to distinguish cell layers, by evaluating beams of light as they are directed at the retina and variably reflected back. Thus, OCT can differentiate between detachment of the retina and that of the RPE, distinguish retinal detachments from schisis cavities, establish the presence of subretinal exudation or neovascular membranes, identify discontinuities in the RPE, and monitor the resolution of subretinal fluid during treatment. Recently, modification of this imaging technique through enhanced depth imaging–OCT (EDI-OCT) has been used to evaluate choroidal changes in various diseases, such as ICSC and VKH disease.

### Fluorescein Angiography and Indocyanine Green Angiography

Imaging of the retinal and choroidal vasculature using fluorescein and ICG is critical in elucidating the different patterns of posterior segment disease, as well as in providing in vivo evidence of the likely pathological mechanisms, as seen in recent ICGA studies of ICSC showing choroidal hyperpermeability underlying areas of serous detachment. These imaging techniques help distinguish various diseases, identify specific areas of leakage, and can direct focal laser treatment and PDT, if necessary.

### Optical Coherence Tomography Angiography

By utilizing flow differences between sequential B-scans, optical coherence tomography angiography (OCTA) can generate a rapid, noninvasive angiographic picture of the retinal vessels and the underlying choroidal

vasculature, as well as abnormal vascular patterns, such as neovascular membranes. Although demonstrations of consistent diagnostic utility are pending, early studies utilizing OCTA showed promise in the management of pathologies that involve disruptions of macular blood flow (Fig. 6.40.6).

## Computed Tomography and Magnetic Resonance Imaging

The broader imaging modalities of CT and MRI can also be used to evaluate posterior ocular and retrobulbar pathology associated with serous retinal detachment, such as with orbital cellulitis. Appropriate use of contrast in these studies can improve evaluation of inflammatory and neoplastic disease.

## DIFFERENTIAL DIAGNOSIS

- Retinoschisis.
- Tractional retinal detachment.
- Rhegmatogenous retinal detachment.
- Choroidal detachment.
- Retinal or subretinal cyst.
- Choroidal or retinal tumor.

## TREATMENT

As mentioned earlier, treatment of serous retinal detachments must address the underlying local or systemic disease, which includes antibiotic therapy (retinal and choroidal infections, orbital cellulitis), systemic immunosuppression (posterior scleritis, vasculitides, autoimmune disease, idiopathic frosted branch angiitis), blood sugar or blood pressure management, or chemotherapy (choroidal neoplasms, multiple myeloma, and BDUMP). In some diseases (e.g., ICSC), simple observation is sufficient. Timely consultation with other medical specialists, when indicated to initiate treatment, is critical.

Additionally, certain ocular treatments can address more focal pathologies, most notably laser photocoagulation in the treatment of vascular anomalies (Coats' disease) and tumors (capillary hemangiomas). In ICSC that does not resolve spontaneously, focal laser can be applied to sites of RPE leakage that are sufficiently distant from the fovea. Laser can also be applied to well-circumscribed choroidal hemangiomas, although external beam radiotherapy is indicated for more diffuse lesions.

PDT has been recently employed for the treatment of other types of choroidal disease, although the complication of vision loss associated with choroidal infarct remains a serious concern. Improvement of serous detachments in ICSC, most especially the chronic form, with half- and minimal-fluence treatments has been demonstrated.

Given the presence of VEGF in a number of retinal diseases, including exudative AMD, Coats' disease, and choroidal melanomas and hemangiomas, the use of intravitreal anti-VEGF therapy can be valuable in the treatment of these etiologies of serous retinal detachment. Intravitreal and peribulbar corticosteroids are also used for treating inflammatory diseases.

Finally, in certain cases of serous retinal detachment, surgical intervention is warranted. The creation of scleral windows in uveal effusion syndrome serves as one example of a primary surgical intervention. However, in occasional cases of inflammatory disease or ICSC, especially with long-standing bullous detachments, surgical intervention has been used with some benefit when all other options have been exhausted.

## COURSE AND OUTCOME

Variable etiologies make for variable outcomes, and the disease courses associated with serous retinal detachment range from the most acute to the most chronic. As a rule, resolution of subretinal fluid occurs with observation or appropriate treatment of the underlying local or systemic pathology. However, the longer a serous detachment is present, the less likely it is that full resolution and, more importantly, restoration of visual function can be achieved. Involvement of the macula also portends a poorer outcome. Visual outcomes with serous detachment tend to be better than with chronic rhegmatogenous and tractional detachments, and this can help to reassure patients as appropriate treatment is initiated.

**Definition:** A hemorrhage in the suprachoroidal space that can occur spontaneously, intraoperatively, or traumatically, or is associated with intraocular vascular anomalies.

## Key Features

- One or more dome-shaped choroidal protrusions.
- Forward movement of the iris, lens, and vitreous body.
- Elevated intraocular pressure.

## Associated Features

- Intraoperative darkening of the red reflex.
- Intraoperative excessive bleeding of conjunctiva and episcleral tissues.
- Severe pain, even under local anesthetic.
- Breakthrough vitreous hemorrhage.
- Rhegmatogenous, exudative, or tractional retinal detachment.

## INTRODUCTION

Choroidal hemorrhage is a serious ocular condition that may be associated with permanent loss of visual function. Both limited and massive choroidal hemorrhages may occur as complications of most forms of ocular surgery and from trauma. Despite modern vitreoretinal techniques, choroidal hemorrhage is associated with visual loss in most cases.

## EPIDEMIOLOGY AND PATHOGENESIS

Choroidal hemorrhage may occur in a limited form or as a massive event. Massive choroidal hemorrhage is of sufficient volume to cause extrusion of intraocular contents outside the eye or to move retinal surfaces into or near apposition (“kissing”). Massive choroidal hemorrhage may be expulsive or nonexpulsive, immediate (intraoperative), or delayed hours to weeks postoperatively; it may occur spontaneously, with choroidal mass lesions (e.g., choroidal hemangioma), or with surgical or noniatrogenic trauma.<sup>1-3</sup>

Limited choroidal hemorrhage occurs in over 3% of intracapsular cataract extractions and in 2.2% of nucleus-expression extracapsular cases.<sup>1</sup> It appears to be less common with small incision phacoemulsification techniques. Massive choroidal hemorrhage has complicated 0.2% of cataract extractions and 0.73% of glaucoma filtering procedures.<sup>2</sup> It may occur even more frequently with keratoplasty.<sup>3</sup> Scleral buckling procedures and pars plana vitrectomy may be complicated by either limited or massive choroidal hemorrhage.

Choroidal hemorrhage may occur when a fragile vessel is exposed to sudden compression and decompression events. An intact posterior lens capsule may serve as a tamponade against such intense intraocular decompression during surgery.<sup>3</sup> Retrobulbar anesthetic injection, retrobulbar hemorrhage, or excessive pressure on the globe during surgery may impede vortex venous outflow and lead to choroidal effusion and hemorrhage.<sup>4</sup> Decompression hypotony, created when the eye is entered, and repeated fluctuations in intraocular fluid dynamics may add further insult

to these fragile vessels. The resultant suprachoroidal effusion progresses to stretch the suprachoroidal space and cause further tension on the ciliary vessels. Alternatively, chronic hypotony may facilitate the extension of a pre-existing suprachoroidal effusion toward the anterior ciliary arteries. Either pathway may result in vessel-wall rupture and suprachoroidal hemorrhage. Modifiable risk factors identified for delayed choroidal hemorrhage post pars plana vitrectomy include emesis and extensive use of photocoagulation.<sup>5</sup>

Systemic conditions that may serve as risk factors for massive choroidal hemorrhage include advanced age, arteriosclerosis, hypertension, diabetes mellitus, blood dyscrasias, and obesity. Ocular risk factors include previous surgery, aphakia, glaucoma, uveitis, high myopia, trauma, vitreous removal, laser photocoagulation, and choroidal sclerosis. A scleral buckle placed during vitrectomy is a risk factor for postoperative choroidal hemorrhage. Glaucoma procedures, previous pars plana vitrectomy, and old age serve as risk factors for appositional choroidal hemorrhage.<sup>6</sup> A history of choroidal hemorrhage serves as a risk factor for surgery on either eye. Intraoperative risk factors include increased intraocular pressure, increased axial length, open-sky procedures, and Valsalva maneuvers. Intraoperative tachycardia has been identified as a significant risk factor or an early symptom of expulsive hemorrhage.<sup>7</sup>

The risks of choroidal hemorrhage may be minimized by control of known risk factors. Preoperative massage and a Honan balloon may be used in cases where peri- or retrobulbar anesthetic is used. Intraoperative temporary security sutures may be placed before planned or conversion to an expression delivery of the lens. The watertight wound created for phacoemulsification helps to maintain intraocular turgor; it may reduce the incidence and limit the severity of suprachoroidal hemorrhage.

## OCULAR MANIFESTATIONS

Both serous and hemorrhagic choroidal detachments usually decrease vision. Serous choroidal detachment may be asymptomatic, but hemorrhagic choroidal detachment often is painful—sometimes extremely so. Slit-lamp examination reveals a shallow anterior chamber with mild cellular reaction and flare. Ophthalmoscopy demonstrates a smooth, bullous, orange-brown elevation of the retina and choroid. Choroidal detachment that occurs anterior to the equator often extends in an annular fashion around the globe; whereas postequatorial choroidal detachment often is unilobulated or multilobulated, secondary to the periequatorial attachment of the choroid at the vortex vein ampullae. Visualization of the ora serrata without scleral depression may be a sign of pre-equatorial choroidal detachment (Fig. 6.41.1).

Eyes with limited and massive (delayed) hemorrhagic choroidal detachments generally have elevated intraocular pressure, and the detachments do not transilluminate, may extend to the posterior pole, and are more voluminous posterior to the equator.

The initial intraoperative symptoms of massive choroidal hemorrhage may be paroxysmal onset of severe intraoperative pain despite adequate analgesia. Classically, the pain radiates from the brow to the vertex of the head along the V1 dermatome and is often refractory to further retrobulbar analgesia. The intraoperative signs of massive choroidal hemorrhage may include tachycardia and excessive iris movement or prolapse. This usually is accompanied by forward movement of the lens and vitreous body as the globe tenses. There is an increasing tendency for suprachoroidal

**Fig. 6.41.1 Hemorrhagic Choroidal Detachment Viewed Ophthalmoscopically.** (A) The extent of choroidal protrusion, as evidenced by a fundus photograph focused on the optic nerve. (B) The dome-shaped lobules and orange-brown color of a choroidal detachment. (C) A closer view demonstrates no subretinal fluid, helping to establish that this is a choroidal detachment, not a retinal detachment.

**Fig. 6.41.2 A-Scan Echogram.** This demonstrates intravitreal opacities and the highly reflective, double-peaked, wide spike characteristic of choroidal detachment.

hemorrhage to manifest as the cataract procedure progresses. The peak may occur during irrigation/aspiration maneuvers.<sup>8</sup> Darkening of the red reflex may precede or accompany a choroidal elevation that protrudes into the operative field. Expulsion of intraocular contents may ensue.

## DIAGNOSIS AND ANCILLARY TESTING

The intraoperative diagnosis of massive choroidal hemorrhage is based on recognition of early signs and changing ocular dynamics. Such recognition requires a high index of suspicion. Similarly, the diagnoses of delayed massive choroidal hemorrhage and limited choroidal hemorrhage are made after recent ocular surgery by consideration of the risk factors, symptoms, and signs. Measurement of intraocular pressure, gonioscopy, slit-lamp biomicroscopy, and dilated fundus examination, comparing both eyes, lead the examiner toward the diagnosis.

When the media is opaque or clear, echography may help to establish an accurate diagnosis and may be employed to differentiate serous from hemorrhagic choroidal detachment.<sup>9</sup> An A-scan echogram demonstrates a lesion with medium-high internal reflectivity and a steeply rising, 100% high spike. At low gain, this is observed to be a double-peaked wide spike characteristic of choroidal detachment (Fig. 6.41.2). The first peak may represent the surface of the overlying detached retina or the anterior surface of the choroid. Alternatively, the double peak may represent both the anterior and posterior surfaces of the choroid. On B-scan echograms, a choroidal detachment typically appears as a smooth, thick, dome-shaped membrane in the periphery that exhibits little if any aftermovement on kinetic evaluation. Serous detachment is characterized by low-reflective fluid in these dome-shaped spaces. Ultrasound may be a helpful prognostic tool for determining final visual outcomes when measured in correlation with choroidal hemorrhage severity.<sup>10</sup>

Hemorrhagic detachment with fresh blood clots is seen echographically as a high-reflective, solid-appearing mass, with irregular internal structure and irregular shape. Serial ultrasonography may demonstrate liquefaction of hemorrhage; the suprachoroidal space is filled with low-reflective mobile opacities that have replaced the hemorrhagic clot.<sup>9</sup> Serous elevation of the retina may accompany choroidal detachment and often resolves spontaneously. Clinically, and on ultrasound, the resolution of the retinal detachment may occur days to weeks after resolution of the choroidal elevation. It is imperative to monitor this and ensure that no retinal breaks are associated or develop.

## DIFFERENTIAL DIAGNOSIS

Differential diagnosis consists of choroidal effusion, rhegmatogenous retinal detachment, and melanoma or metastatic tumor of choroid or ciliary body.

## TREATMENT

### Primary Management

The management of serous choroidal detachment usually is conservative. Postoperative serous choroidal detachments often resolve on their own within days. Cycloplegia and topical corticosteroids are general

management measures. Surgical management of serous choroidal detachment may be indicated for refractory progressive shallowing or flattening of the anterior chamber. The threat of corneal decompensation after lens–cornea touch or the apposition of retinal surfaces in kissing choroidal detachment are other potential indications for surgical intervention.

Delayed nonexpulsive limited choroidal hemorrhage generally carries a good prognosis. Limited choroidal hemorrhage usually resolves spontaneously within 1–2 months without ophthalmoscopic evidence of damage. Management remains conservative in this situation and includes the use of cycloplegics and topical corticosteroids. The management of delayed, nonexpulsive, massive choroidal hemorrhage, by contrast, remains controversial. Some reports suggest that irreversible loss of vision may result when intervention does not take place within 1 week. Systemic corticosteroids are employed by some investigators.<sup>11</sup> Surgical drainage should be considered in the following circumstances:

- Massive choroidal hemorrhage associated with severe pain.
- Elevated intraocular pressure.
- Persistently flat anterior chamber.
- Suprachoroidal hemorrhage under the macula.
- Extension of hemorrhage into the subretinal space or vitreous cavity.

Significant vitreous incarceration in the surgical wound and kissing choroidal detachments, which may lead to secondary subacute traction or rhegmatogenous detachment after resolution of the suprachoroidal hemorrhage and its classic “buckle-like” effect, also are potential indications for surgical drainage.<sup>12</sup>

In 1915, Voerhoeff introduced posterior sclerotomy to release suprachoroidal blood for the management of massive choroidal hemorrhage. Intraoperative massive choroidal hemorrhage is managed by tamponade of the eye with direct digital pressure and rapid wound closure. The use of high-viscosity viscoelastics to control anterior chamber depth and progressing intraocular hemorrhage has been advocated.<sup>13</sup> The goal of rapid wound closure is to prevent expulsion or loss of the intraocular contents and incarceration of vitreous or retina in the surgical wound.

## Secondary Management

Choroidal hemorrhage that occurs postoperatively, recurs, or meets indications for further surgical intervention should be managed by a vitreoretinal surgeon. The successful management of affected eyes requires that vitreous or retinal incarceration be relieved completely. Patients who have vitreous incarceration are at high risk of developing retinal detachment. Eyes with concurrent vitreous and retinal detachment, at the time of diagnosis, may not be amenable to surgical repair or may be at high risk for proliferative vitreoretinopathy. Surgical intervention to drain choroidal hemorrhage ideally is conducted after liquefaction of the suprachoroidal hemorrhage, which may be assessed by serial echography.<sup>9</sup> Recent reports highlight the successful use of tissue plasminogen activator to achieve earlier clot lysis.<sup>14</sup> Three-dimensional reconstruction of the B-scan is possible with modern ultrasonography. This may assist in localization of the best sites for surgical drainage (Fig. 6.41.3).

The timing of such intervention may be altered by the presence of rhegmatogenous retinal detachment. The primary surgical goal is to separate any kissing choroidal detachments to prevent secondary traction or rhegmatogenous retinal detachment. Surgical goals should also include the separation of kissing choroidal detachments by one-half of their original height.

The initial stages of surgical drainage of massive choroidal hemorrhage include conjunctival peritomy and isolation of the relevant rectus muscles with bridle sutures. Often, all four rectus muscles are isolated to enable exposure if posterior drainage sclerotomies are needed in multiple quadrants to evacuate adequately the suprachoroidal hemorrhage.

Infusion of fluid or air to pressurize the eye and allow more complete evacuation of the suprachoroidal hemorrhage generally is a useful adjunctive procedure. The anterior chamber is entered with a 25-gauge or smaller needle, bent posteriorly, so that the bevel directs the infusion away from the corneal endothelium. Alternatively, a micro-vitreo-retinal blade may be used if a self-retaining or sutured infusion cannula is to be inserted (Fig. 6.41.4). Again, flow should be directed posteriorly. Viscoelastic agents may be employed to deepen the anterior chamber sufficiently to insert the infusion cannula or replace the need for infusion cannula by injecting them into the vitreous cavity.<sup>15</sup>

Posterior sclerotomy sites generally are created in the area of greatest choroidal elevation, with the patient in the supine (surgical) position to optimize drainage of the hemorrhage. Incisions (4–6 mm long) are created

**Fig. 6.41.3** A Three-Dimensional Ultrasonogram of Choroidal Hemorrhage. A, Anterior; P, posterior.

with a round or sharp blade posterior to the rectus muscle insertions, centered at the equator of the globe. Exposure is best in the inferotemporal quadrant, but other quadrants may be incised to achieve optimal drainage, as judged by inspection and ophthalmoscopy (Fig. 6.41.5). The sclerotomy sites may be sutured closed to restore anatomical integrity and stability or left open if further spontaneous drainage is felt likely or necessary. Another approach is to place the sclerotomies in the pars plana region, allowing easier access and suturing of scleral wounds.

A novel technique using the 25-gauge or 20-gauge transconjunctival trocar/cannula systems to drain serous and hemorrhagic choroidal detachments is gaining popularity, especially in eyes with conjunctival thinning and scarring. It comprises the use of a 25-gauge, 23-gauge infusion line or a 20-gauge Lewicky anterior chamber maintainer to keep the anterior

**Fig. 6.41.4** A Self-Retaining Infusion Cannula in the Anterior Chamber.

**Fig. 6.41.5** Creation of a Posterior Sclerotomy Incision to Drain a Choroidal Hemorrhage.

**Fig. 6.41.6** A 20-Gauge Lewicky Anterior Chamber Maintainer. Notice how the pars plana is easily visible behind the intraocular lens because of the mechanical disposition of the choroidal detachment. The caliber is set to the distance between the limbus and the maximum height of the choroidal detachment (8 mm in this photo).

chamber pressurized (Fig. 6.41.6). Then a 20-gauge or 25-gauge trocar/cannula system is used 7.0 mm from the limbus to create a transconjunctival beveled incision at 1 or 2 quadrants where the suprachoroidal detachment height measures at least 7 mm (Fig. 6.41.7) (Video 6.41.1). After drainage, the cannula is removed and the conjunctiva over the incision is cauterized.<sup>16</sup>

If vitreous is incarcerated in the original surgical wound, a vitrectomy probe may be introduced through a second limbal incision and an anterior vitrectomy performed to minimize vitreoretinal traction during the choroidal drainage procedure. Once adequate initial drainage has been achieved, a posterior vitrectomy with scleral depression may be performed to remove residual lens fragments, cortex, and vitreous adhesion to the iris. In the

**Fig. 6.41.7** Transconjunctival Trocar/Cannula Drainage Technique. Diagram illustrating the 25-gauge anterior chamber infusion line and the trocar/cannula inserted 7 mm from limbus away from uveal tissue. Cannula is directed toward the equator, which allows complete drainage without entering the vitreous cavity.

absence of retinal detachment, this may be deferred to later surgical intervention. For rhegmatogenous retinal detachment, a more extensive posterior vitrectomy in conjunction with drainage of the choroidal hemorrhage usually is necessary. Relaxing peripheral retinotomy or retinectomy may be necessary to relieve incarceration of the retina or severe anterior vitreous traction. The use of perfluorocarbon liquids may facilitate the drainage of suprachoroidal hemorrhage and facilitate reattachment of the retina.<sup>17</sup> Scleral buckling or long-term intraocular tamponade with silicone oil may minimize the chances of recurrent retinal detachment in these eyes.<sup>11</sup> The tamponading effect of 100% perfluoropropane (C3F8) was found to be helpful in early drainage of massive suprachoroidal hemorrhage.<sup>18</sup> Preoperative systemic corticosteroids may offer a better primary repair rate.<sup>11</sup>

Central retinal apposition in retinal detachment that follows drainage of choroidal fluid poses a unique surgical challenge. Perfluorocarbon liquids may be used to stabilize the posterior retina. A taper-tip endocautery can preserve hemostasis as the retinal surfaces are teased or cut apart to separate them. The perfluorocarbon level can be raised further to flatten the now-separated surfaces. Endolaser treatment and gas or oil tamponade may then be used. The reduction of risk factors for choroidal hemorrhage should achieve foremost attention at the time of secondary lens implant.<sup>19</sup>

## Choroidal Hemorrhage in Trauma

Choroidal hemorrhage that occurs with noniatrogenic trauma or rupture of the globe may be associated with intraocular structural damage. In addition to contusive injury, fibrocellular proliferation with membrane formation may limit the visual rehabilitation of the eye.<sup>20</sup> The management of these cases must take into consideration the high likelihood of retinal detachment and associated proliferative vitreoretinopathy. Surgery may require evacuation of hyphema. Corneal blood staining may necessitate the use of a temporary keratoprosthesis. The choroidal hemorrhage is drained as described above. Scleral buckling and long-term tamponade with silicone oil may be required to effect repair of an associated rhegmatogenous retinal detachment. The echographic characteristics of choroidal hemorrhages that result from trauma differ from those that arise from other causes. In general, traumatic choroidal hemorrhages tend to be more diffuse and less elevated (Fig. 6.41.8).<sup>9</sup>

## Choroidal Hemorrhage in Other Conditions

Choroidal hemorrhage may occur in association with hemoglobinopathies, with the use of systemic anticoagulants or tissue plasminogen activator,

**Fig. 6.41.8** Transverse B-Scan of an Eye After Repair of a Ruptured Globe. The annular, flat, and diffuse hemorrhagic choroidal detachment is typical of trauma.

**Fig. 6.41.9** A Hemorrhagic Choroidal Detachment Seen in a Patient Using Warfarin. (Courtesy Jeffrey L. Marx, MD.)

with coughing,<sup>21</sup> or spontaneously (Fig. 6.41.9). In one series, patients developed acute angle-closure glaucoma from forward displacement of the lens-iris diaphragm, which resulted from massive hemorrhagic detachment of the choroid and retina. Affected patients often have associated systemic hypertension or a primary or anticoagulant-induced clotting disorder.<sup>22</sup> The source of “spontaneous” hemorrhage in these patients is often choroidal neovascularization in a disciform lesion.

Sturge-Weber syndrome is characterized by a flat, facial hemangioma that follows the distribution of the fifth cranial nerve. Choroidal and episcleral hemangiomas are seen commonly. Trabeculectomy in these cases is complicated by rapid expansion of the hemangioma, with effusion of fluid into the suprachoroidal and subretinal space in 17% of cases. Some surgeons recommend placement of two or three posterior sclerotomies to prevent such expansion. Definitive management includes posterior drainage sclerotomy followed by reformation of the anterior chamber.<sup>23</sup>

Limited choroidal hemorrhage can be mistaken for a choroidal melanoma. Fluorescein angiography and ultrasonography may help to differentiate these entities.<sup>21,24</sup>

## COURSE AND OUTCOME

Delayed, nonexpulsive, limited choroidal hemorrhage generally carries a good prognosis. Choroidal hemorrhages in cataract surgery tend to fare better than those in other forms of ocular surgery or in trauma. Retinal detachment in an eye with choroidal detachment or with choroidal hemorrhage in all four quadrants correlates with a poor visual outcome.<sup>2,25</sup> The extension of suprachoroidal hemorrhage into the posterior pole has been associated with worse visual and anatomical outcomes.<sup>26</sup> Vitreous and, especially, retinal incarceration are associated with a poorer prognosis.<sup>27</sup> Eyes with appositional choroidal detachment, duration of apposition greater than 30 days, a history of uveitis, macular degeneration, or extracapsular cataract extraction are associated with poor visual acuity outcomes.<sup>6</sup> In the absence of retinal adherence, however, kissing choroidal detachments may not portend a worse outcome—the natural history of this condition has not been delineated precisely.

# Proliferative Vitreoretinopathy

Sidath E. Liyanage, David G. Charteris, G. William Aylward

# 6.42

**Definition:** The proliferation of avascular fibrocellular retinal membranes associated with rhegmatogenous retinal detachment.

## Key Features

- Epiretinal and subretinal fibrous proliferation.
- Contraction of membranes.
- Recurrent or persistent retinal detachment.
- Retinal shortening.
- Reopening of pre-existing retinal breaks.
- Formation of new retinal breaks.

## Associated Features

- Hypotony.
- Vitreous opacity.
- Aqueous flare.
- Iris neovascularization.
- Macular pucker.

## INTRODUCTION

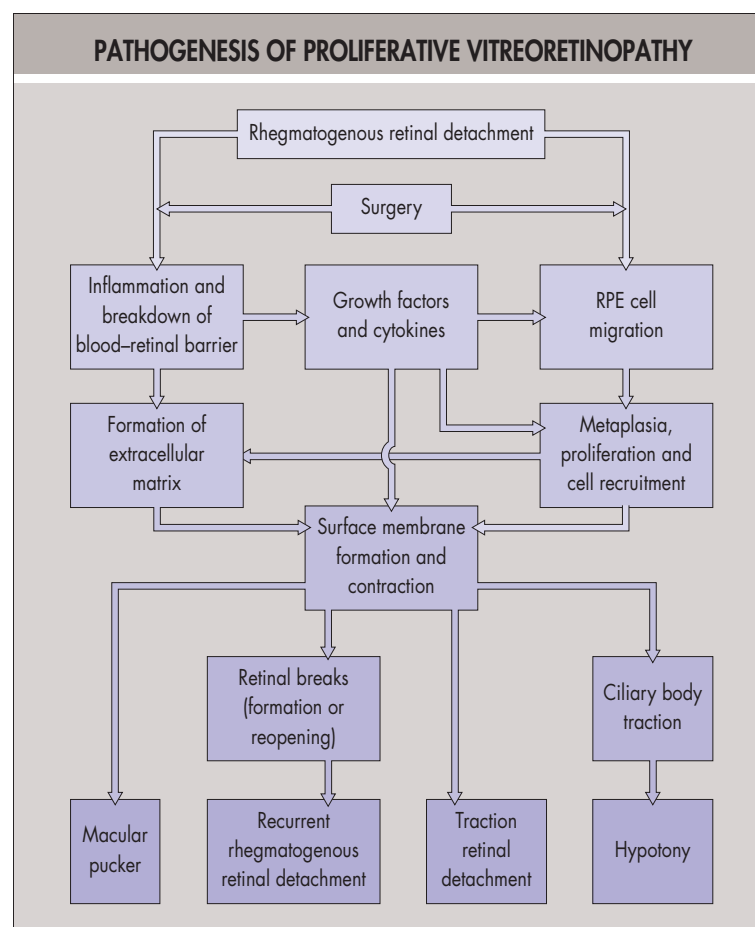

Proliferative vitreoretinopathy (PVR) is the most common cause of ultimate failure after surgical treatment for rhegmatogenous retinal detachment.<sup>1,2</sup> A wound-healing response, PVR is characterized by the formation of surface membranes in the posterior segment. Membranes most commonly form on the inner surface of the neural retina but can also be found in the subretinal space, in the vitreous base, and on the ciliary body. Contraction of these membranes may cause macular pucker, new retinal breaks, recurrent retinal detachment, and ocular hypotony.

## EPIDEMIOLOGY AND PATHOGENESIS

PVR occurs following surgical repair of retinal detachment but can develop in untreated cases, particularly those that are long-standing or with large breaks. It may also occur following large choroidal detachments or in eyes with large, treated retinal tears but no previous retinal detachment. It occurs in 5%–10% of treated rhegmatogenous retinal detachment cases and represents the major cause of ultimate surgical failure,<sup>1</sup> a situation that is unchanged despite advances in vitreoretinal surgical technology, including small-gauge technology.<sup>3,4</sup>

Certain types of retinal detachments are more likely to develop PVR than others. For example, those associated with giant retinal tears (greater than 3 clock hours) have a high incidence of postoperative PVR. Other risk factors have been identified in several studies that used multivariate regression analysis. These include the number and size of retinal breaks, the number of previous operations, the presence of choroidal effusions, the use of cryotherapy, intraocular hemorrhage, aphakia, high vitreous protein levels, and the severity of preoperative PVR.<sup>2,3,5,6</sup> Young patients who have penetrating trauma, especially double perforating injuries, also have a very high risk of PVR.

The pathogenesis of PVR is multifactorial and is summarized in Fig. 6.42.1. The primary event is the formation of a retinal break. Upregulation of the retinal response to injury with retinal glial activation then ensues and plays a central role in PVR development.<sup>3,7</sup> Retinal pigment epithelium (RPE) cells then migrate through the break into the preretinal space, where they settle on the retinal surface. Most of the fibrocellular tissue develops inferiorly, which suggests that gravity influences the distribution

**Fig. 6.42.1 Pathogenesis of Proliferative Vitreoretinopathy.** The flow chart illustrates the interaction of various factors in the pathogenesis of proliferative vitreoretinopathy, from the initial retinal detachment to the serious complications of recurrent detachment and hypotony.

of the RPE cells. Glial cell proliferation and extension of glial processes to the epi- and subretinal spaces follows, and an extracellular matrix is laid down.<sup>7</sup> These cells take on the characteristics of myofibroblasts in that they have contractile elements and deposit collagen.<sup>2</sup> Although the cellular origins of PVR are critical, the extracellular environment plays a decisive role as well. Inflammation and breakdown of the blood–retina barrier are associated with further cellular recruitment modulated by inflammatory mediators and the formation of extensive fibrous membranes.<sup>8</sup> Collagen is produced and the membranes then contract. It is the contraction of surface membranes that produces the clinical features described below. The cycle of cell dispersion, inflammation, membrane formation, and contraction with eventual redetachment of the retina has a typical timescale of 4–6 weeks after the initial detachment.

## OCULAR MANIFESTATIONS

The clinical spectrum of PVR varies according to the extent and location of membranes and the presence and position of retinal breaks. Epiretinal membrane formation after successful retinal detachment surgery can be considered a mild form of PVR (Fig. 6.42.2). In its most severe form, membrane contraction produces a total, funnel-shaped detachment with

**Fig. 6.42.2 Macular Pucker Following Retinal Detachment Surgery.** Contraction of a surface membrane at the macula produces symptoms of distortion and reduced visual acuity. Such epiretinal membranes are identical histologically to those removed from elsewhere on the retina in proliferative vitreoretinopathy.

**Fig. 6.42.3 Star Fold From Proliferative Vitreoretinopathy.** Contraction of a focal retinal surface membrane has resulted in the formation of a star fold. In this case, membranes can also be seen on the posterior surface of the partially detached hyaloid face.

retina adherent anteriorly to the ciliary body and even to the iris, which results in hypotony and phthisis bulbi.

The earliest signs of PVR include marked vitreous flare and clumps of pigment in the vitreous. Increased stiffness of the detached retina often occurs, which can be detected with indirect ophthalmoscopy while the patient's eye is making saccades. A fresh retinal detachment without PVR appears to undulate under these conditions, an undulation that is reduced if significant surface membranes are present. The edges of retinal breaks may be rolled over, as a result of contraction on one surface only, and retinal breaks may appear stretched open. Star folds represent localized areas of puckering in detached retina after focal, localized contraction (Fig. 6.42.3).

Subretinal fibrosis may accompany surface membranes to give a “Swiss cheese” appearance to the subretinal space. Some of the subretinal sheets of membrane coil together, which results in broad, subretinal strands.

## RETINAL SHORTENING

**Fig. 6.42.4 Retinal Shortening.** Surface membrane contraction can result in retinal shortening, which prevents break closure and retinal reattachment.

**TABLE 6.42.1 Proliferative Vitreoretinopathy: Retina Society Revised Classification**

Grade A	Vitreous haze, pigment clumps, decreased mobility of posterior hyaloid face
Grade B	Inner retinal wrinkling, stiffness, rolled edges of retinal breaks
Grade C	Full-thickness retinal folds, anterior/posterior extent in clock hours
Type 1	Focal posterior contraction (star fold)
Type 2	Diffuse posterior contraction
Type 3	Subretinal bands/sheets
Type 4	Circumferential contraction (posterior edge of vitreous base)
Type 5	Anterior displacement of vitreous base

From Machemer R, Aaberg TM, MacKenzie Freeman H, et al. An updated classification of retinal detachment with proliferative vitreoretinopathy. *Am J Ophthalmol* 1991;112:159–65.

A subretinal “napkin ring” of membrane can surround the peripapillary retina to produce a tight posterior funnel configuration and obscure the optic nerve. Significant amounts of surface traction produce retinal shortening, which makes break closure and retinal reattachment impossible (Fig. 6.42.4). More severe contraction may pull the anterior retina inward, which leads to an anterior funnel appearance. In severe cases, closure of the anterior end of the funnel may make it impossible to visualize the optic disc even if the posterior retina is relatively unaffected. Contraction of the vitreous base leads to circumferential shortening and anterior loop contraction. Surface membranes on the ciliary body may compromise aqueous production, which results in hypotony.

Surface membranes can be difficult to diagnose when the retina is attached. Histopathological examination of the majority of successfully repaired retinal detachments show surface membrane formation. Occasionally, surface membranes can result in localized traction retinal detachments, often seen just posterior to a scleral buckle. These localized traction detachments tend to be stable and should be differentiated from recurrent rhegmatogenous detachments associated with open retinal breaks. Traction retinal detachments have a concave surface generated by the RPE pump pulling against traction, in contradistinction to the convex profile of rhegmatogenous detachments. Should a new retinal break develop acutely or a pre-existing break reopen, already present but unsuspected membranes may result in dramatic contraction of the newly redetached retina to give the clinical impression of sudden development of severe PVR.

Associated anterior segment signs include anterior chamber cells and flare and low intraocular pressure. In some eyes, dilated iris vessels or even iris neovascularization develops.

The Retina Society devised a classification scheme for PVR that has been used in clinical trials of treatment.<sup>9</sup> The initial scheme did not distinguish between anterior and posterior PVR, and improvements in the understanding of anterior PVR have led to a modification of the classification (Table 6.42.1).<sup>10</sup> Anterior PVR is characterized by contraction of

## ANTERIOR PROLIFERATIVE VITREORETINOPATHY (1)

**Fig. 6.42.5 Anterior Proliferative Vitreoretinopathy (1).** Fibrous contraction in an anteroposterior direction in the region of the vitreous base pulls up a loop of retina to produce retinal shortening. Coexistent traction on the ciliary body produces hypotony.

## ANTERIOR PROLIFERATIVE VITREORETINOPATHY (2)

**Fig. 6.42.6 Anterior Proliferative Vitreoretinopathy (2).** Contraction of the anterior vitreous produces a funnel configuration.

membranes associated with the vitreous base; it is seen most commonly after failed vitrectomy and gas tamponade for retinal detachment or after penetrating trauma.<sup>11</sup> Anteroposterior traction can pull a fold of retina forward to produce a “trough” with posterior shortening (Fig. 6.42.5), which can be difficult to diagnose preoperatively. Circumferential contraction of the vitreous base produces radial folds in the retina, and perpendicular contraction of the anterior vitreous leads to an anterior funnel-shaped configuration (Fig. 6.42.6).

## DIAGNOSIS

In eyes with clear media, the diagnosis of PVR is straightforward. A history of retinal detachment surgery and the clinical features just described do not generally present a diagnostic problem. In eyes with opaque media, B-scan ultrasonography is necessary to reveal the stiffened, detached retina and associated membranes.

### BOX 6.42.1 Differential Diagnosis of Proliferative Vitreoretinopathy

- Proliferative diabetic retinopathy with traction retinal detachment
- Chronic retinal detachment with retinal edema and/or cyst formation
- Severe choroidal detachments
- Severe vitreomacular traction syndrome with traction retinal detachment
- Severe ocular hypotony

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis of PVR is given in Box 6.42.1.

## SYSTEMIC ASSOCIATIONS

Although no specific systemic associations exist, patients who have Stickler’s syndrome have an increased risk of retinal detachment due to large and/or multiple retinal breaks that make subsequent PVR likely.

## PATHOLOGY

A large body of pathological information exists that confirms the role of glial activation, RPE cells, inflammation, breakdown of the blood–ocular barrier, macrophages, growth factors, cytokines, clotting cascade proteins, adhesion molecules, and extracellular matrices in the development of PVR. In histological specimens, RPE cells are uniformly present, and evidence shows that they can undergo metaplastic change to macrophages or fibroblasts.<sup>12</sup> Glial cells are a major component of PVR membranes and may arise from retinal astrocytes<sup>13</sup> or from Müller cells extending processes to epi- and subretinal membranes.<sup>3,7</sup> Lymphocytes have been identified in excised PVR membranes,<sup>14</sup> and inflammatory cells may play a role in mediating the proliferative response.

The behavior of the RPE cell may be stimulated by several different growth factors that are known to contribute to the wound-healing process in general. For example, platelet-derived growth factor stimulates chemotaxis,<sup>15</sup> and fibroblast growth factor and insulin-like growth factor-1 stimulate RPE cell proliferation.<sup>16</sup> Elevated levels of bFGF, interleukin-1, and interleukin-6 have been detected in the vitreous of patients with PVR.<sup>17,18</sup> In contrast, transforming growth factor- $\beta$  (TGF- $\beta$ ) has an inhibitory effect on cell proliferation in tissue culture.<sup>19</sup> Replicated genetic association studies have suggested a contribution of the SMAD7 (a TGF- $\beta$ -pathway mediator) and TNF (an inflammatory cytokine) genes to the PVR process.<sup>20</sup>

The extracellular matrix associated with PVR consists of various types of collagen, particularly types I and III. Other components include fibronectin and the basal lamina proteins, heparan sulfate, laminin, and collagen type IV.<sup>21</sup> Modeling of the extracellular matrix by matrix metalloproteinases may play a role in the pathogenesis of PVR.<sup>22</sup>

The mechanism of membrane contraction remains poorly understood. Some of the cell types found in membranes are capable of contraction, including fibroblasts and RPE cells.<sup>23</sup> Cytoplasmic myofilaments have been seen in some fibroblastic cells, but simple motility of cells through a collagen matrix may be sufficient to produce shortening.

The retina, at least in the early stages of PVR, remains relatively well preserved, suggesting the potential for functional recovery.<sup>7,24</sup> Photoreceptor apoptosis has, however, been demonstrated<sup>24</sup> together with remodeling changes in the neural retina,<sup>7</sup> which may have a negative effect on visual recovery. The epiretinal membranes in anterior PVR have focal glial attachments to the underlying retina, which may make surgical separation of these tissues difficult or impossible.<sup>7,24</sup>

## TREATMENT

In the absence of open retinal breaks, PVR does not require treatment unless the macula is involved. Localized traction detachments posterior to a scleral buckle are stable and asymptomatic. Macular pucker after otherwise successful retinal detachment surgery may be responsible for reduced visual acuity and distortion. Such cases often benefit from membrane peeling.

In rhegmatogenous retinal detachment, the choice of treatment is based on the severity and location of the PVR and the location of the retinal break or breaks. Scleral buckling alone may be successful if the surface membranes do not prevent break closure. For example, the presence of

**Fig. 6.42.7 Scleral Buckling in Proliferative Vitreoretinopathy.** The large inferior buckle seen here was used to support inferior breaks associated with proliferative vitreoretinopathy. Recurrent gray proliferative vitreoretinopathy membranes can be seen on the surface of the buckle, but the retina remains attached posteriorly. Note the dark line on the edge of the buckle, which is an optical effect of the silicone oil fill.

**Fig. 6.42.8 Surgery for Proliferative Vitreoretinopathy.** A pick is used to elevate surface membranes prior to removal with forceps.

inferior star folds does not prevent successful closure of a single superior retinal break by means of a scleral buckle. However, it can be difficult to judge the extent of retinal shortening and, therefore, the influence of a star fold on a remote break. If surface membranes occur in close association with retinal breaks, closed intraocular microsurgery with membrane peeling is required to enable break closure, although occasionally a substantial inferior buckle can be used successfully to close breaks associated with a moderate degree of surface contraction<sup>25</sup> (Fig. 6.42.7).

With an internal approach, a complete pars plana vitrectomy is followed by peeling of surface membranes using a combination of a retinal pick and microforceps<sup>26</sup> or curved membrane scrapers (Fig. 6.42.8). The ease with which membranes can be removed varies, and this may be related to membrane-retina glial bridges,<sup>24</sup> but it is important to relieve traction associated with breaks if surgery is to succeed. Perfluorocarbon liquids may assist the process as they highlight the membranes and act as a “third hand” to assist in membrane removal.<sup>27</sup> If long-term intravitreal tamponade with silicone oil is to be used, the membranes may be more visible after oil injection and so are peeled at that stage. If not already present,

**Fig. 6.42.9 A Severe Case of Anterior Proliferative Vitreoretinopathy Treated With a 270° Relaxing Retinectomy.** The line of laser retinopexy at the edge of the retinectomy can be seen to join with an area of chorioretinal adhesion from cryotherapy.

a circumferential scleral buckle is usually applied to support the vitreous base, which typically is shortened circumferentially. Occasionally, peeling of posterior membranes is insufficient to relieve retinal shortening. In such cases, further dissection of the vitreous base may be successful. Alternatively, a relaxing retinectomy can be performed (Fig. 6.42.9).<sup>28,29</sup>

Rarely, subretinal membranes may be present, usually in a band-like configuration. These can tent up the retina, although in most cases simple closure of the break results in complete reattachment. If necessary, the bands can be divided through a small retinotomy or pulled out hand over hand, as they tend to be only loosely adherent to the overlying retina.

After membrane removal, the retina is reattached by means of internal drainage of subretinal fluid, usually accompanied by a fluid–air exchange. Retinopexy with cryotherapy or laser photocoagulation is applied to all breaks. Laser retinopexy is often preferred because of the theoretically increased risk of further PVR associated with the use of cryotherapy.

A long-acting gas or silicone oil is injected for tamponade; the choice of agent depends on a number of factors. The Silicone Study examined the effect of the choice of long-term retinal tamponade on final surgical outcome in PVR cases. The study indicated that both perfluoropropane ( $C_3F_8$ ) gas and silicone oil were of similar benefit in PVR, and both are superior to  $SF_6$ .<sup>30,31</sup> In anterior PVR, the use of silicone oil yields a better visual outcome than  $C_3F_8$ .<sup>32</sup> Silicone oil has certain intraoperative and postoperative advantages over gas, which include improved visualization for retinopexy, less need for positioning, and better vision in the immediate postoperative period.

Recent advances include the utilization of heavier-than-water silicone oils to manage inferior PVR. A randomized controlled trial comparing heavy silicone oil with light silicone oil in eyes with PVR showed no significant differences in either anatomical success or final visual acuity.<sup>33</sup> A systematic review of the above tamponade agents did not highlight any differences in outcomes, suggesting a patient-individualized approach to choice of tamponade.<sup>34</sup>

Despite successful treatment, PVR can recur, which results in the formation of new breaks or the reopening of treated breaks (Fig. 6.42.10). The tendency of PVR to recur has generated much interest in the use of pharmacological agents for adjuvant therapy to surgery. Fig. 6.42.1 shows that many potential pharmacological targets exist for such therapy.

Attempts to modulate the inflammatory component of PVR pathogenesis have been unsuccessful.<sup>35</sup> Randomized controlled trials investigating intraoperative intravitreal triamcinolone<sup>36</sup> and intraoperative slow-release dexamethasone implants<sup>37</sup> have failed to improve anatomical outcomes in cases with established PVR, whereas the use of postoperative oral prednisolone<sup>38</sup> did not influence the development of PVR.

A meta-analysis of the combination of adjuvant 5-fluorouracil (an antimetabolite) and low-molecular-weight heparin as an adjunct in the

**Fig. 6.42.10 Reproliferation and Failed Retinectomy for Proliferative Vitreoretinopathy.** Reproliferation of membranes along the edge of a relaxing retinectomy has resulted in elevation of the posterior edge.

treatment of PVR highlights inconsistent results,<sup>39</sup> reducing the incidence of PVR in high-risk cases undergoing vitrectomy<sup>40</sup> but failing to improve the outcome in cases with established PVR<sup>41</sup> or in preventing the development of PVR in unselected cases.<sup>42</sup>

Perioperative use of daunomycin, another antimetabolite, resulted in a weak beneficial effect in achieving anatomical success in a large randomized controlled trial.<sup>43</sup> A smaller randomized control trial investigating oral isotretinoin in established PVR showed statistically significant improvement in reattachment rates.<sup>44</sup>

## COURSE AND OUTCOME

Untreated, PVR inevitably leads to severe loss of vision, hypotony, and sometimes phthisis bulbi. Success rates of surgical treatment vary and depend on the severity of PVR and the surgical techniques employed.<sup>45,46</sup> Prior to the introduction of closed intraocular microsurgery, success rates were poor. With modern techniques, anatomical success is being achieved in an increasing number of cases. Most recent series report single surgery anatomical success rates of approximately 80% in cases with PVR C.<sup>4,29</sup>

Despite improved anatomical results, visual outcomes are often disappointing.<sup>3,47</sup> When patients have a normal fellow eye, functional vision in the operated eye may not be useful, and it is considered a “spare.”<sup>48</sup> It is notable that vision-threatening pathology has been demonstrated in over

50% of fellow eyes in PVR cases,<sup>49</sup> and this is an important consideration when deciding to operate on PVR cases.

Visual loss in PVR is a combination of photoreceptor degeneration and apoptosis, neural remodeling, and epi- and subretinal pathology.<sup>50</sup> Subretinal gliosis prevents photoreceptor regeneration.<sup>50</sup> Clinically it has been noted that two-thirds of PVR cases with poor visual recovery have cystoid macular edema,<sup>51</sup> and treatment of this with topical corticosteroids and anti-inflammatory medications or potentially intraocular corticosteroid injections may be of value in improving visual outcomes.

# Posterior Segment Ocular Trauma

Gregory D. Lee, John W. Kitchens, Patrick E. Rubsamen

# 6.43

**Definition:** Penetrating and/or nonpenetrating physical trauma to the globe, resulting in damage to the posterior segment.

## Key Features

- Blunt injury with or without globe rupture.
- Penetrating injury with or without foreign body.

## Associated Features

- Hemorrhage.
- Commotio retinae.
- Choroidal rupture.
- Traumatic macular hole.
- Sclopetaria.
- Retinal detachment.
- Proliferative vitreoretinopathy.
- Endophthalmitis.
- Sympathetic ophthalmia.

## INTRODUCTION

Ocular trauma is an important cause of visual loss and subsequent disability. With modern diagnostic techniques and surgical approaches, many eyes can be salvaged with retention of vision.<sup>1-4</sup> Despite advances in medical and surgical management, penetrating trauma continues to be a complicated and challenging condition.

Posterior segment trauma is broadly divided into nonpenetrating and penetrating injuries. Nonpenetrating injuries that involve the posterior segment are the result of severe, blunt, concussive blows to the globe and result in specific types of ocular damage such as commotio, choroidal rupture, traumatic macular hole, and sclopetaria.

Penetrating injuries are divided into various subcategories based on specific types of injuries. Penetrating injuries can occur secondary to blunt force trauma, lacerating injuries, or injuries associated with intraocular foreign bodies.

## OCULAR MANIFESTATIONS AND CLINICAL EXAMINATION

### History

Clinical history is essential to ascertain important details about the mechanism of injury. A careful history as to the circumstances surrounding the injury can help elucidate the type of injury (blunt trauma, penetrating injury with or without foreign body), the potential for secondary complications (clean vs. contaminated or “dirty” wound), and the potential for other associated nonocular injuries (e.g., the potential for a subdural hemorrhage in an elderly patient after a fall). Finally, a comprehensive medical history should be obtained with specific attention directed toward active medical conditions, current medications (specifically anticoagulants), drug allergies, and history of tetanus immunization.

## Clinical Examination

The initial clinical examination should be as comprehensive as possible while avoiding iatrogenic injury to the eye. Visual acuity may be difficult to accurately assess in the setting of severe ocular trauma. Pupillary examination should be assessed for the presence of an afferent pupillary defect, which can be an important objective assessment of the visual potential of the injured eye. Care should be taken to limit the examination of extraocular motility due to the potential extrusion of ocular contents. Ocular tonometry should be deferred in the setting of a potential ruptured globe.

Slit-lamp evaluation with minimal pressure on the globe should be performed with attention toward finding any open lacerations of the cornea or sclera. Extensive subconjunctival hemorrhage in the setting of a hypotonus globe should raise the suspicion for an occult rupture that cannot be directly visualized. Early signs of infection such as inflammation should be ascertained.

If the fundus can be visualized, then the presence of a penetrating injury with or without foreign body (IOFB) should be by ophthalmoscopy. Identification of retinal tears, retinal detachment, and choroidal hemorrhage are critical prior to surgical intervention. Retinal vasculitis and diffuse intraretinal hemorrhages can be an important harbinger of endophthalmitis. In the setting of blunt trauma, macular and peripheral evaluation are important to identify the various manifestations of nonpenetrating trauma.

## Ancillary Testing

Ancillary testing is useful in the evaluation of patients who have penetrating injuries or in patients with poor visualization of the fundus. Standard orbital plain film radiographs will delineate the presence of a radiopaque foreign body (Fig. 6.43.1). Radiolucent foreign bodies such as wood or glass will often not be visualized with plain films. Computed tomography (CT)

**Fig. 6.43.1 Radiopaque Intraocular Foreign Body (arrow).** Note the characteristic acoustic shadowing (A) behind it.

scanning of the orbits is more helpful in not only determining the presence of a radiopaque foreign body but also localizing the foreign body. It is important to order axial, coronal, and lateral, fine-section images (2-mm “cuts”) to help precisely localize the IOFB. Magnetic resonance imaging (MRI) is contraindicated in any patient with a potential magnetic IOFB. Diagnostic ultrasound can help detect and localize IOFBs that are radiolucent. Ultrasound can also help to assess the amount of liquefaction of the hemorrhage in cases where choroidal hemorrhage is present. Liquefaction of choroidal hemorrhage often occurs within 7–14 days after occurrence. It is at this time that drainage can occur most effectively.

## NONPENETRATING TRAUMA

Blunt injury to the globe can result in a variety of anterior segment manifestations that can affect the management of the posterior segment. Corneal edema can preclude an adequate view of the posterior segment. Anterior chamber hemorrhage (hyphema) can also reduce or eliminate visualization into the back of the eye. Subluxation or dislocation of the crystalline lens may require removal via a posterior approach.

### Comotio Retinae

Comotio retinae is retinal whitening/opacification that results from a blunt injury. The ocular findings will often resolve in a matter of days to weeks. Vision loss can result from commotio involving the posterior pole (historically referred to as Berlin’s edema, [Fig. 6.43.2](#)).<sup>5</sup> It is a common retinal finding after significant ocular injury occurring in up to half of all cases of significant blunt trauma.<sup>6</sup> Histopathological studies show that the findings are localized to the outer retina. These findings are supported by optical coherence tomography (OCT) that shows increased reflectivity of the inner and outer segments.

Clinical findings of commotio include the characteristic retinal whitening. Comotio may result in significant vision loss that can be transient. Healing can result in pigmentary changes and retinal thinning that may be associated with poor visual recovery if the area of involvement is macular. Areas of involvement outside of the macula can result in peripheral visual field loss and retinal pigment epithelium (RPE) changes that can mimic sectoral retinitis pigmentosa (RP), acute zonal occult outer retinitis (AZOOR), chronic central serous, and similar conditions.

Diagnostic testing in the setting of commotio should include OCT testing to identify the extent of photoreceptor involvement. Photography to document the extent of the involvement is often useful in these cases.

Management of collateral injuries is of most importance as there is no therapy for commotio. The prognosis for commotio is variable.

### Choroidal Rupture

Choroidal rupture often occurs as the result of blunt trauma ([Fig. 6.43.3](#)). It represents a tear not only in the choroid but also in the RPE and Bruch’s membrane. It is the disruption in Bruch’s membrane that results in the late complication of this condition, choroidal neovascularization. Choroidal ruptures can occur anteriorly (due to direct concussive force of the blunt trauma) or posteriorly (due to indirect blunt force).

Clinical findings of choroidal rupture acutely include the presence of a curvilinear defect of the RPE and choroid. Often this area has associated subretinal hemorrhage. The initial hemorrhage is due to the rupture of the choroid. Often this hemorrhage will clear within a few weeks. Remote from the initial injury, choroidal neovascularization can develop resulting in vision loss remote to the initial trauma.

Initial diagnostic testing in the setting of choroidal rupture can include OCT and photography. If the development of choroidal neovascularization is suspected, OCT and fluorescein angiography can be very helpful in determining the presence and extent of the abnormal vessels.

Therapy of choroidal rupture is limited. Visual acuity will often depend on the involvement of the foveal center by the rupture. The late occurring sequela of choroidal neovascularization can result in loss of vision. Patients should be made aware of this potential occurrence and should be given and instructed on use of an Amsler grid for detection of choroidal neovascularization, should it occur. Intravitreal antivascular endothelial growth factor therapy is very effective in the management of these vessels.

### Traumatic Macular Hole

Full-thickness macular hole formation can result from blunt ocular trauma. Macular hole formation can occur immediately after trauma or

may develop several weeks to months after the injury. The exact mechanism of macular hole formation in this setting is unknown, but acute anteroposterior vitreous traction is suspected. Macular hole formation can also be seen after severe blunt trauma in association with commotio and retinal hemorrhage. OCT can aid in identifying the progressive retinal changes leading to the development of the macular hole. Often, cystic intraretinal or subretinal findings can be visualized on OCT prior to the onset of the full-thickness defect. Patients with good visual acuity after their initial injury will often notice the development of a central scotoma, whereas those without good visual acuity due to associated injuries may not be able to discern any differences. Biomicroscopy and OCT testing are critical to the diagnosis of a posttraumatic full-thickness macular hole.

Pars plana vitrectomy with intravitreal gas tamponade is the primary therapy for this condition. Timing of surgery is controversial, as some traumatic macular holes close spontaneously. Traumatic macular holes may carry a poorer prognosis for surgical closure due to their size. Visual improvement may be limited due to concomitant injuries.

### Chorioretinitis Sclopetaria

Chorioretinitis sclopetaria (CRS) is a simultaneous break in the retina and the choroid that occurs as a result of a high-velocity object coming in contact with the globe without penetrating the eye ([Fig. 6.43.4](#)). The simultaneous retraction of the choroid and retina at the site reveals the bare sclera.<sup>7</sup> The site of involvement can be adjacent to the impact site or remote from the site. Remote (or indirect) areas of involvement can result in significant damage to the macula.

Clinically, visual acuity is often limited due to the mechanism and severity of the injury. Hemorrhage is often present around the area of CRS in either the preretinal or subretinal space. There is often surrounding commotio present. The sclera is often readily visible through the defect in the retina/choroid. With time, the surrounding areas develop a pigmentary response and scar formation ensues. Initially, clinicians are concerned that the area of injury may develop into a retinal detachment. Often with observation, this does not occur.

Therapy is limited. If the patient develops significant, vision-limiting vitreous hemorrhage or a retinal detachment ensues, then surgery with vitrectomy and/or scleral buckling is warranted. The prognosis is poor in cases that involve the macular area.

### Retinal Tear

Trauma is responsible for about 5% of all retinal detachments.<sup>8</sup> As such, blunt trauma can result in the precursor to retinal detachment, the retinal tear. Traumatic posterior vitreous detachment can result from compressive forces within the eye. The incidence of retinal tear formation in blunt trauma is unknown. More severe blunt trauma and predisposing factors such as myopia and the presence of lattice degeneration increase the risk of developing a retinal tear.

Patient symptoms consistent with a posterior vitreous detachment, including “flashes and floaters,” should alert the examiner to the possible presence of peripheral pathology secondary to the trauma. Clinical examination is critical in diagnosing a traumatic retinal tear. Slit-lamp biomicroscopy to determine the presence of pigmented vitreous cell should be performed. Vitreous hemorrhage is suggestive of a possible retinal tear. Indirect ophthalmoscopy should take place to thoroughly examine the peripheral retina. Depressed examination is also essential, but associated injuries should be assessed prior to proceeding with indentation of the eye wall to prevent exacerbation of anterior chamber hyphema. Additionally, concomitant injuries may prohibit depressed examination secondary to patient discomfort.

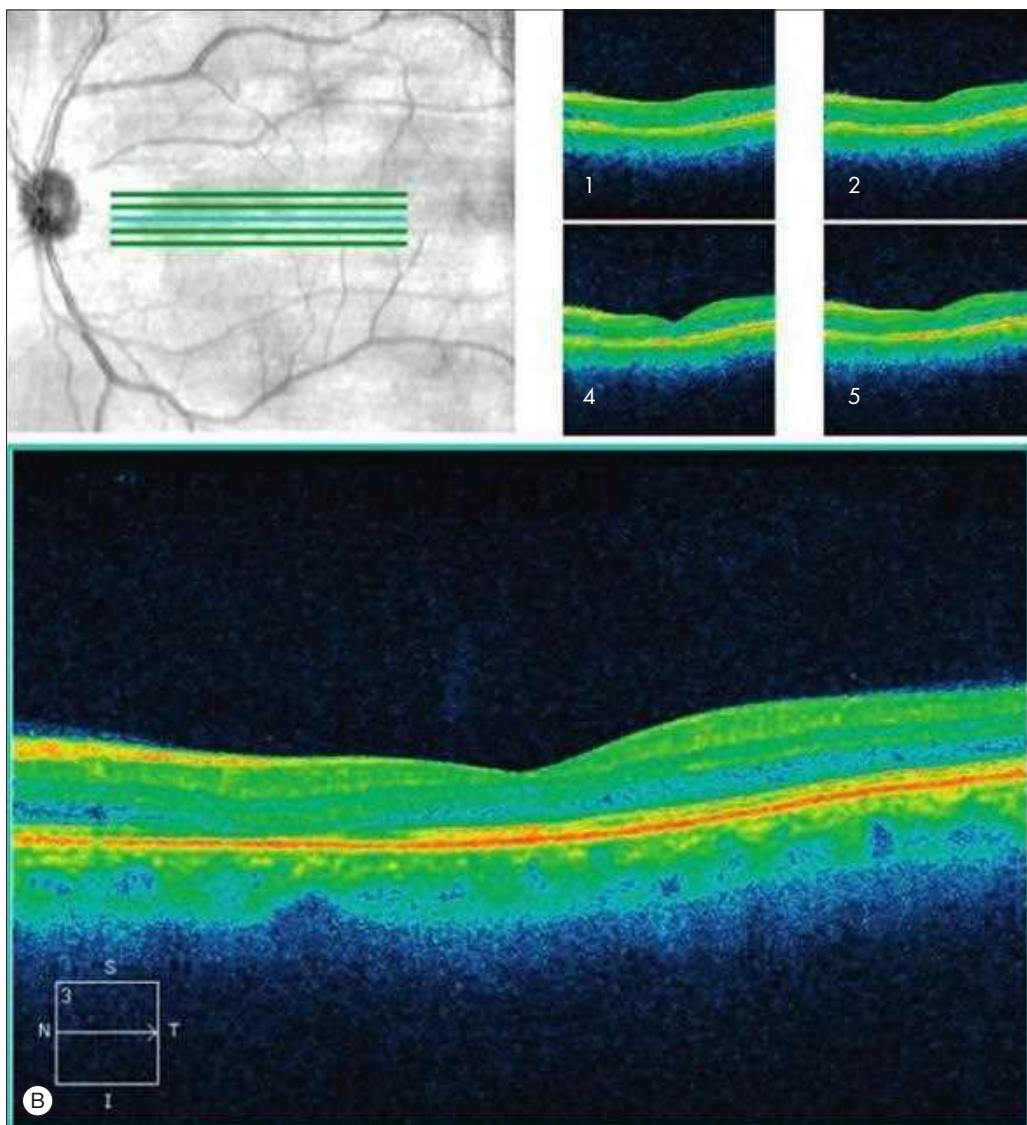

Treatment of a retinal tear with prophylactic laser therapy is essential to prevent retinal detachment. Care should be taken to differentiate a traumatic retinal tear from CRS, which is often more extensive, results in a defect of both the retina and choroid, and requires no treatment to prevent retinal detachment.

### Retinal Detachment

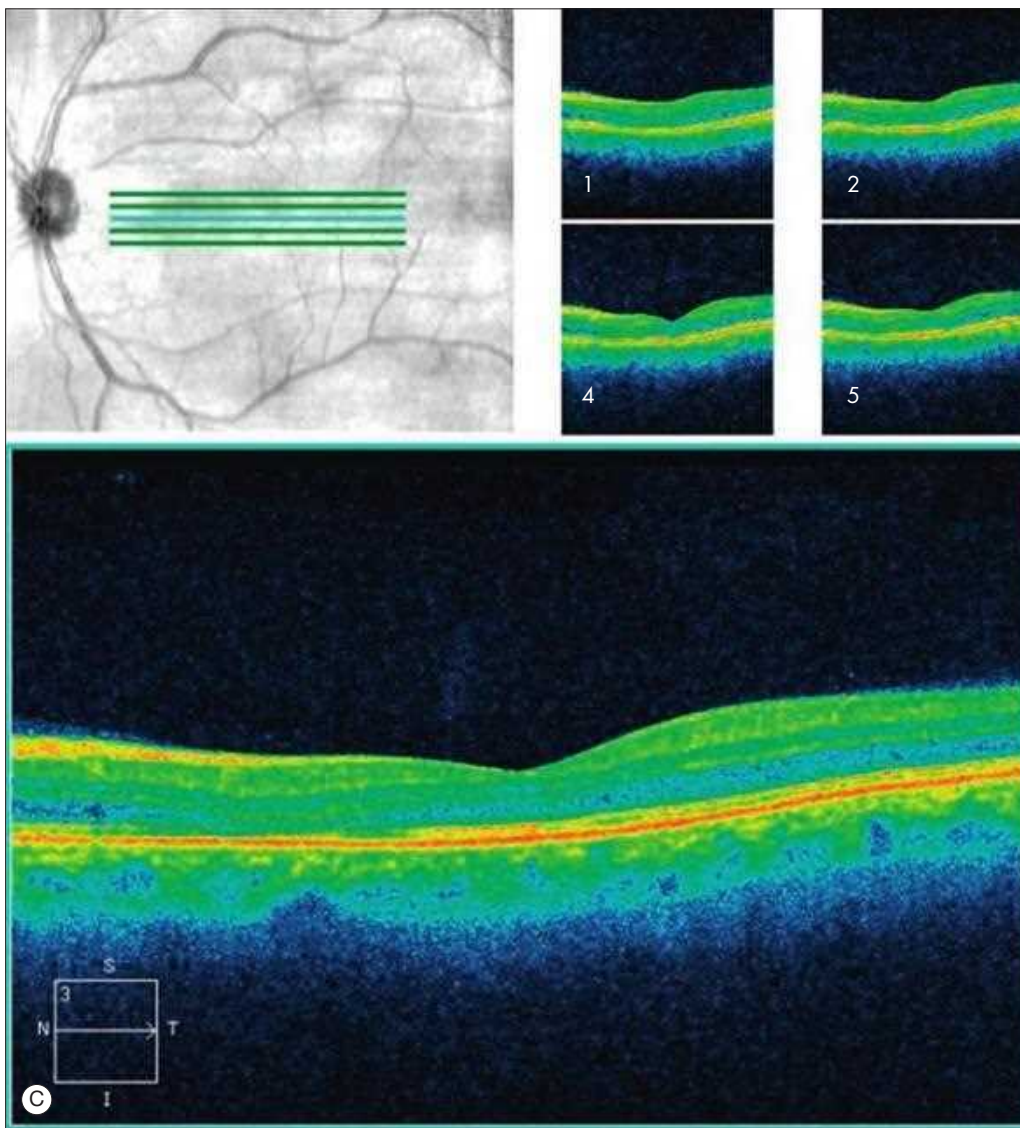

Blunt and penetrating trauma both represent significant risk factors for the development of retinal detachment. Blunt trauma can result in retinal tears secondary to a vitreous detachment (see earlier). Retinal detachment in the setting of blunt trauma can also result from a retinal dialysis (see later).

**Fig. 6.43.2** (A) Berlin's edema (commotio retinae) in a patient after blunt trauma. (B) Acute optical coherence tomography (OCT) findings demonstrate disruption of the outer retina.

**Fig. 6.43.2, cont'd** (C) After resolution of the acute findings, the OCT shows outer retinal atrophy including photoreceptor loss. (B–C courtesy Drew Sommerville, MD; Talley Eye Care; Evansville, IN.)

**Fig. 6.43.3 Choroidal Rupture With Vitreous Hemorrhage and Commotio.** NOTE: Blunt trauma from a broken exercise band resulted in commotio and choroidal rupture nasal to the optic nerve. Vitreous hemorrhage also resulted (A). One month later, the commotio has resolved and the choroidal rupture can be well visualized (B).

**Fig. 6.43.4 Gunshot Wound to the Periocular Region.** (A) Sclopetaria manifests as subretinal and choroidal hemorrhage; also note marked disruption and necrosis of the choroid and retina. (B) After 6 months and no surgical intervention, the retina remains attached and marked chorioretinal scarring is present.

Clinically, retinal detachment in the setting of blunt trauma can occur acutely or remote from the traumatic event. In either case, a careful history of the symptoms is critical. The examination should include biomicroscopy to determine if the macula is involved by the detachment (macula/fovea—on/off). In addition, associated injuries such as commotio, choroidal rupture, and macular hole must be assessed. Injury to the anterior segment—hyphema, angle recession, traumatic cataract, and intraocular lens (IOL) dislocation—can also affect surgical planning and disposition. Ocular ultrasonography can be of benefit when visualization of the posterior segment is obscured by vitreous hemorrhage or opacities of the anterior segment.

As with other causes of retinal detachment, treatment centers on surgical repair. Most commonly scleral buckling, pars plana vitrectomy, or a combination of both is employed to repair traumatic retinal detachments. In addition, injuries to the anterior segment such as traumatic cataract or IOL dislocation may necessitate surgical management at the time of the retinal detachment (RD) repair.

## Retinal Dialysis

Retinal dialysis is a tearing of the retina at the ora serrata due to an avulsion of the vitreous base from sudden traction at the vitreous base. Not all dialyses are traumatic in nature, and a developmental abnormality may be responsible for most of the nontraumatic cases. Dialyses are most

commonly seen in the inferotemporal quadrant. When a dialysis occurs in the superior or nasal areas, trauma should be strongly suspected.

Clinical examination is critical in diagnosing a retinal dialysis. A peripheral depressed examination is almost essential to differentiate a retinal dialysis from a giant retinal tear, as a dialysis will not fold back on itself or become inverted due to the presence of the vitreous base adherent to the edge of the retina.

Treatment for a retinal dialysis without an associated retinal detachment includes observation (particularly if there is RPE hyperplasia posterior to the area of dialysis) and laser or cryotherapy. In the setting of a retinal detachment, a scleral buckle with cryotherapy is effective in repairing the detachment in over 90% of eyes. If the subretinal fluid is shallow, often a nondrainage buckle is effective. Care must be taken when performing vitrectomy surgery in cases of retinal detachment secondary to retinal dialysis in younger patients, as their vitreous may be formed and more difficult to separate during surgery.

## Retinal Pigment Epithelium Contusion/Traumatic Choroidopathy

RPE contusion occurs because of blunt trauma that results in RPE damage and leakage acutely. This leakage can cause a serous retinal detachment that resolves within 3 weeks of the initial injury. Remote from the injury, angiography can show increased transmission through the damaged RPE. Visual acuity often is normal if the foveal area is spared or minimally involved. There is no treatment for this condition.

Traumatic choroidopathy is a rare result of significant blunt trauma. Choroidal nonperfusion can result in contusion necrosis to the RPE, which can result in a serous retinal detachment. Often with such significant blunt trauma, commotio can also be present. Angiography will demonstrate multifocal areas of leakage at the level of the RPE in the acute setting. Visual prognosis is poor in these cases.

## Macular Hemorrhage

Intraretinal or subretinal hemorrhage can occur in cases of blunt ocular trauma. Intraretinal hemorrhage can be isolated or occur with other findings of trauma, including commotio or macular hole formation. Subretinal hemorrhage should suggest the possibility of a choroidal rupture. Careful follow-up observation is necessary to identify the rupture site as the hemorrhage resolves. In isolated cases of hemorrhage, observation is usually warranted, as often it will resolve without significant vision loss.

## Optic Nerve Avulsion

Optic nerve avulsion (ONA) is a visually devastating condition that results from severe blunt or penetrating trauma. Vision is profoundly affected, with most patients demonstrating no light perception vision. Absence or recession of the optic nerve head is present on examination if associated injuries permit visualization of the posterior pole. Often there will be surrounding hemorrhage around the area in question. There is no treatment for this devastating complication of trauma.

## PENETRATING TRAUMA

Management of penetrating injuries varies according to the severity, extent, and location of the injury, as well as the presence or absence of an IOFB. The general principles of management of a penetrating injury to the eye include:

- Primary closure of the wound.
- Removal of any foreign body material.
- Prevention of secondary complications from the injury (retinal detachment or infection).
- Anatomical and visual rehabilitation of the eye.
- Protection of the fellow eye (protective eyewear; enucleation in rare instances to reduce the risk of sympathetic ophthalmia).
- General rehabilitation of the patient.

## Initial Closure

In cases of penetrating eye injuries, primary closure of the globe is the first priority. Posterior penetrating injuries should be closed as meticulously as possible. A scleral laceration is often best closed utilizing either 9-0 or

8-0 nylon sutures in an interrupted fashion. Occasionally, running sutures may be required in cases that have poor potential for wound apposition with traditional suturing techniques. Prolapse of intraocular contents can occur with manipulation of the globe, so great care must be taken with surgical exploration to prevent this from occurring. Scleral lacerations extending posterior to the equator may require some gentle pressure to allow for full visualization. Very posterior lacerations (such as those that occur with “through-and-through” perforating injuries) can self-seal if given ample time. For penetrating injuries that involve the vitreous base, a prophylactic scleral buckle may reduce the risk of a subsequent retinal detachment.<sup>2</sup> In addition, this can minimize the need to reopen scarred tissues in the area of the laceration for subsequent surgeries.

## INTRAOCULAR FOREIGN BODIES

IOFBs should be removed at the time of initial closure if possible. The presence of an IOFB increases the risk of endophthalmitis. Prompt surgical removal may be associated with a decreased risk of clinical infection.<sup>9-11</sup> Intraocular foreign bodies that are metallic can be removed by either intraocular forceps or utilizing a rare earth magnet or external electromagnet (most useful for IOFBs located in anterior vitreous adjacent to the pars plana, Videos 6.43.1 and 6.43.2).

See clip:  
6.43.1  
and  
6.43.2

## Metallosis

Metallosis occurs when certain types of metallic IOFBs are not removed promptly from the eye (Fig. 6.43.5). Damage occurs as a result of oxidation and other chemical reactions with the surrounding tissues.<sup>12,13</sup> Iron and copper are the two most common alloys responsible for metallosis. Iron-containing IOFBs result in siderosis. Siderosis often manifests itself months to years after the injury and can result in heterochromia, RPE degeneration (peripheral initially), and a gradually progressive loss of vision. Copper-containing alloys with less than 85% copper cause chalcosis. Chalcosis can result in a Kayser–Fleischer ring, greenish heterochromia, sunflower cataract of the anterior capsule, and refractile deposits in the macular region, often with peripheral sparing. Copper alloys of greater than 85% result in a sterile endophthalmitis. Prompt and complete removal of the IOFB is essential in the management of these sequelae.

## Secondary Infection

Aside from damage from the primary injury, endophthalmitis is the most significant consequence of a penetrating eye injury. The mechanism of injury is the greatest determining factor for the development of infection, and so a careful history should be ascertained. A variety of techniques are used for prophylaxis of infection. First, if there is an adequate view to

**Fig. 6.43.5 Copper Intraocular Foreign Body.** Acute presentation of a patient with a penetrating wire injury. (Courtesy Andrew Pearson, MD and Drew Sommerville, MD; University of Kentucky Department of Ophthalmology.)

the posterior segment with no contraindications to the administration of intravitreal injections, then antibiotics can be administered as a pars plana injection. This route of administration ensures that the highest concentration of antibiotics reaches the area of greatest concern for infection. If the view to the posterior segment is compromised, then intracameral antibiotics can be considered. The role of intravenous antibiotics in the setting of a ruptured globe injury is controversial because of poor ocular penetration, particularly with vancomycin. However, systemic administration of moxifloxacin has been shown to achieve minimum inhibitory concentrations in both noninjured and injured eyes.<sup>14</sup>

## Rehabilitation: Secondary Surgical Timing

Timing and approach to the surgical repair of disrupted intraocular structures after penetrating injury are dependent on the nature and severity of the initial trauma. There are two general approaches to the timing of surgery: initial closure/delayed repair and simultaneous closure/repair. The first approach involves an initial closure of the rupture site along with the placement of a scleral buckle if indicated. This is then followed 4–10 days later by a vitrectomy. The benefit of this approach is improved visualization through the cornea and reduced intraocular bleeding. The second approach of simultaneous closure and repair allows for earlier removal of blood and lens remnants from the eye, which may reduce the risk of complicated retinal detachment secondary to proliferative vitreoretinopathy (PVR, Fig. 6.43.6). It may also reduce the need for a second surgery. There are two circumstances in which delayed secondary surgery would be preferred: if there is a posterior exit wound that cannot be closed at the time of repair, and massive hemorrhagic choroidal detachments.

**Fig. 6.43.6 Hemorrhagic Retinal Detachment in a Patient After an Ice-Pick Stab Wound.** (A) Note the incarceration of the retina in the posterior impact site (arrow) and the subretinal blood (curved arrow). A localized choroidal hemorrhage is seen in the foreground on the left. (B) Postoperative appearance after vitrectomy, removal of subretinal blood, and extraction of retina from the area of incarceration (scar).

## Rehabilitation: Surgical Technique

Vitreotomy permits the rehabilitation of many eyes that previously would have been lost after penetrating injury. A three-port technique is used most commonly. In cases of poor visualization to the posterior segment, it is important to identify choroidal or retinal detachments preoperatively. This is best accomplished with ultrasonography. Placement of the infusion cannula is a critical first step. A longer infusion cannula (6 mm vs. the traditional 4 mm cannula) and more anterior placement may avoid sub-retinal or suprachoroidal placement. Placement of infusion through the anterior chamber may be necessary in cases where there are appositional choroidal detachments or a total retinal detachment with little room for traditional pars plana infusion placement. The second consideration must be given to obtaining an adequate view to the posterior segment. Anterior chamber hemorrhage and lens damage must be addressed to visualize the posterior segment. Considerable hemorrhage can occur from the injured ocular structures, further inhibiting the view. Although small-gauge surgery has improved significantly with newer generations of equipment, posterior segment trauma in the setting of both primary and secondary repair as well as removal of IOFBs may benefit from larger gauge instrumentation.

Complicated PVR may occur in eyes after penetrating injury. PVR can manifest as severe membrane formation on the surface of the retina. It is often associated with a retinal detachment. Repair of a PVR-related retinal detachment requires release of the membranes during vitrectomy, laser photocoagulation to create a chorioretinal adhesion, reattachment of the retina using gas or oil tamponade, and often the placement of a scleral buckle to support the peripheral vitreous. In cases of extensive membrane formation or in instances where a foreign body penetrates the retina causing retinal incarceration in the wound, it is necessary to perform a retinectomy to release traction on the retina and allow it to reoppose the eye wall.

## Traumatic Endophthalmitis

Endophthalmitis in the setting of penetrating trauma usually carries a poor prognosis.<sup>15,16</sup> This results from both the injury itself and the damage caused by the infection. Contributing to the poor outcome may be the delay in treatment, difficulty administering antibiotics in a standard manner, and virulence of the organisms involved (e.g., *Bacillus cereus*). Risk of traumatic endophthalmitis varies depending on the circumstances of the injury (rural injuries having a higher incidence),<sup>17</sup> retained IOFB,<sup>9-11</sup> and injury to the crystalline lens.<sup>11</sup> Endophthalmitis should be suspected when inflammation is present, including hypopyon, retinal vasculitis, and vitritis (Fig. 6.43.7). Management of traumatic endophthalmitis includes obtaining cultures from either the vitreous (preferred) or the anterior chamber. Broad-spectrum antibiotics should be administered intravitreally if possible. Vancomycin adequately covers common Gram-positive organisms

**Fig. 6.43.7 Traumatic Endophthalmitis (*Streptococcus faecalis*) at Presentation After Penetrating Trauma.** Note the marked anterior chamber fibrin, early ring infiltrate of the cornea, peripheral hypopyon, and purulent material in the area of corneal laceration.

(*Staphylococcus* and *Streptococcus*) and *Bacillus*. Cefazidime provides additional Gram-negative coverage without the risk of vascular occlusion associated with intravitreal gentamicin. The simultaneous administration of intraocular corticosteroids is controversial. If antibiotics cannot be administered intravitreally because of the presence of a retinal detachment or extensive hemorrhagic choroidal detachments, then intracameral and/or systemic antibiotics can be used. Topical antibiotics may be useful as an adjuvant.

## COURSE AND OUTCOME

### Prognosis

Prognosis is related to the severity of the injury and complications that develop secondary to the injury. Several variables are associated with the long-term prognosis:

- Initial visual acuity.
- Presence of an afferent pupillary defect.
- Severity of the initial injury (size and location of the initial wound).
- Presence of an IOFB.
- Presence of infection.
- Presence of extensive hemorrhagic choroidal detachments.
- Presence or occurrence of a retinal detachment.
- Posterior exit wound.

A scoring system has been proposed to better estimate the visual potential after an ocular injury. This scoring system helps give a more accurate estimate of the potential for visual recovery.<sup>18</sup>

### Sympathetic Ophthalmia

Sympathetic ophthalmia (SO) is a rare but potentially devastating consequence of penetrating injury.<sup>19</sup> It manifests as a bilateral granulomatous inflammatory response. SO is presumed to be caused by sensitization of the immune system to uveal antigens. The majority of cases occur between 3 weeks and 3 months of the initial injury, but patients can present years after the initial injury with symptoms of uveitis (pain, photophobia, loss of vision). Bilateral panuveitis is the most common finding. Treatment of SO involves the use of oral, topical, or periocular corticosteroids, initially often with more prolonged therapy involving immunomodulatory agents. Early enucleation (within two weeks of the initial injury) is believed to reduce the risk of developing SO and should be considered for severely traumatized eyes with no visual potential. Despite the rarity of the condition, it is important to advise the patient of this possibility after penetrating trauma.

### Additional Considerations

It is critical to emphasize the need for protective eyewear for patients who have suffered vision loss from ocular trauma. Use of polycarbonate eyewear should be prescribed and encouraged. In young children, the potential for amblyopia exists in the traumatized eye. Thus an eye with good visual potential should undergo treatment for amblyopia if the child is in the appropriate age range.

Traumatic eye injuries not only impart significant vision loss but also can have a tremendous psychological impact on patients. Depression and anxiety are commonplace in this setting. Psychological support is often necessary in helping to overcome these obstacles. In addition, patients with significant vision loss in one eye require assistance in adjusting to a monocular life. Low vision services and rehabilitation therapy are important considerations. An additional resource is the book *A Singular View: The Art of Seeing With One Eye* by Frank Brady.

# Distant Trauma With Posterior Segment Effects

Jason Hsu, Carl D. Regillo

# 6.44

## TERSON SYNDROME

**Definition:** Intraocular hemorrhage associated with acute intracranial hemorrhage.

### Key Features

- Bilateral, multiple posterior segment hemorrhages.
- Intraretinal, preretinal, or intravitreal location.

### Associated Features

- Spontaneous or trauma-induced intracranial blood (usually subarachnoid).
- Decreased vision with good spontaneous recovery.

## PURTSCHER RETINOPATHY

**Definition:** Peripapillary retinal infarctions associated with severe trauma or various systemic conditions.

### Key Features

- Bilaterally symmetrical peripapillary cotton-wool spots.
- Bilateral retinal hemorrhages.

### Associated Features

- Severe head, chest, or long bone injury.
- Amniotic fluid embolism.
- Pancreatitis.
- Other rare systemic conditions.
- Decreased vision with variable or limited recovery.

## SHAKEN BABY SYNDROME

**Definition:** Intraocular hemorrhage that results from whiplash-like child abuse.

### Key Features

- Bilateral retinal or vitreous hemorrhage.
- No evidence for direct eye trauma.

### Associated Features

- Intracranial hemorrhage (usually subdural).
- Cerebral edema or atrophy.
- Decreased vision.
- Variable recovery as a result of ocular or central nervous system damage.

## TERSON SYNDROME

### INTRODUCTION

In 1900, Terson reported the association of vitreous hemorrhage with an acute subarachnoid hemorrhage. The syndrome that now bears his name has evolved to include cases with any type of intraocular hemorrhage present after spontaneous or trauma-induced intracranial bleeding.<sup>1</sup>

### EPIDEMIOLOGY AND PATHOGENESIS

Intraocular hemorrhage is seen in approximately 20% of patients with acute intracranial bleeding.<sup>1,2</sup> Significant vitreous hemorrhage occurs in a smaller percentage of these patients, being observed in 3%–5% of all patients with intracranial bleeding. The intracranial hemorrhage can be subdural, subarachnoid, or intracerebral in location. Subarachnoid bleeding from a cerebral aneurysm, in particular an anterior communicating artery aneurysm, is the most common underlying cause.<sup>2</sup>

The pathogenesis of Terson syndrome remains controversial. Some investigators initially assumed that the intraocular hemorrhage resulted from dissection of the subarachnoid hemorrhage down the optic nerve sheath and into the eye.<sup>1</sup> The lack of communication between the subarachnoid space of the optic nerve and vitreous renders this mechanism unlikely. Furthermore, the retinal hemorrhages are often not contiguous with the optic nerve, and autopsy studies have not shown that the optic nerve sheath hemorrhage extends to the globe.<sup>3</sup>

It is now believed that the sudden rise in intracranial pressure that occurs at the time of the intracranial bleed is the primary event that leads to intraocular bleeding.<sup>2</sup> In support of this is the observation that the amount of ocular hemorrhage correlates directly with the rapidity and magnitude of intracranial pressure elevation. How increased intracranial pressure translates into intraocular bleeding remains unclear. Potential explanations include increased orbital venous pressure translated directly through the cavernous sinus or compression of both the ophthalmic vein and adjacent retinochoroidal anastomoses due to a rapid effusion of cerebrospinal fluid or blood into the optic nerve sheath.<sup>1-4</sup> In either scenario, an acute obstruction to the retinal venous circulation results and leads to the rupture of superficial retinal vessels.

### OCULAR MANIFESTATIONS

Terson syndrome consists of multiple, usually bilateral, retinal hemorrhages in the posterior pole (Fig. 6.44.1). Visual acuity is often diminished, but this may not be easily quantified when the neurological manifestations predominate. The amount of acute vision loss is typically related to the extent of intraocular hemorrhage. Although hemorrhages can be subretinal and intraretinal, they are usually more superficial, being under the internal limiting membrane or preretinal (subhyaloid). Significant vitreous hemorrhage is possible, probably from blood that breaks through the internal limiting membrane or posterior hyaloid face into the vitreous gel. Late complications include epiretinal membrane formation, macular holes, perimacular retinal folds, and, rarely, traction or rhegmatogenous retinal detachments.<sup>5,6</sup>

### DIAGNOSIS AND ANCILLARY TESTING

The typically devastating consequences of acute intracranial hemorrhage, rather than the intraocular consequences, lead the patient to seek medical

**Fig. 6.44.1 Terson Syndrome.** Multiple superficial intraretinal hemorrhages and preretinal hemorrhage in an eye of a patient who had suffered intracranial bleeding from head trauma. (Courtesy Lon S. Poliner, MD.)

#### BOX 6.44.1 Differential Diagnosis of Terson Syndrome

- Purtscher retinopathy
- Shaken baby syndrome
- Valsalva retinopathy
- Blood dyscrasia

attention. In such patients, the diagnosis of Terson syndrome is generally obvious on ophthalmic evaluation. It may be an important diagnosis to establish because the presence of intraocular hemorrhage may be associated with a higher mortality than when no ocular involvement occurs.<sup>7,8</sup> In suspected cases without established intracranial hemorrhage, emergency neuroimaging is indicated.

### DIFFERENTIAL DIAGNOSIS

The differential diagnosis for Terson syndrome is given in [Box 6.44.1](#).

### TREATMENT AND OUTCOME

In Terson syndrome, the blood typically clears completely and the visual acuity returns to normal.<sup>1,2</sup> However, in some cases the vision remains decreased from persistent vitreous hemorrhage or epiretinal membrane formation. In such situations, vitrectomy to clear the hemorrhage or remove membranes can improve the visual outcome.<sup>7,9</sup> Timing of vitrectomy does not seem to influence final outcomes, although the rare associated retinal detachment requires urgent surgical intervention.<sup>10</sup>

Occasionally some vision loss may persist as a result of subretinal hemorrhage that has disrupted the retinal pigment epithelium (RPE) or direct damage to the outer retina in the foveal area.

## PURTSCHER RETINOPATHY

### INTRODUCTION

In 1910, Purtscher described the occurrence of bilateral patches of retinal whitening and hemorrhage around the optic disc in patients who suffered massive head trauma.<sup>11</sup> Subsequently, this appearance was observed with other trauma, along with a variety of nontraumatic systemic diseases such as acute pancreatitis, systemic lupus erythematosus, thrombotic thrombocytopenic purpura, and chronic renal failure.<sup>12–14</sup>

### EPIDEMIOLOGY AND PATHOGENESIS

Clinical and experimental data suggest that Purtscher retinopathy results from occlusion of small arterioles by intravascular microparticles generated

**Fig. 6.44.2 Purtscher Retinopathy Associated With Thrombotic Thrombocytopenic Purpura.** (A) At presentation. (B) After 4 months of follow-up. Peripapillary retinal whitening and hemorrhage slowly resolved to leave macular pigment mottling and optic disc pallor. Visual acuity remained unchanged in the counting fingers range. (Copyright 1997, American Medical Association. With permission from Power MH, Regillo CD, Custis PH. Thrombotic thrombocytopenic purpura associated with Purtscher retinopathy. *Arch Ophthalmol* 1997;115:128–9.)

by the underlying systemic condition.<sup>1,12,13,15,16</sup> These microparticles may consist of fibrin clots, platelet-leukocyte aggregates, fat emboli, air emboli, or other particles of similar size that block the arterioles in the peripapillary retina. In experimental animal studies, fibrin clots 0.15–1.0 mm in size injected into the ophthalmic artery produced a Purtscher-like fundus.<sup>15</sup>

### OCULAR MANIFESTATIONS

Patients experience acute, painless loss of central vision in one or both eyes that is often marked. Ophthalmoscopy reveals multiple, variably sized cotton-wool spots, inner retinal whitening (“Purtscher flecken”), and intraretinal hemorrhages around the optic nerve ([Fig. 6.44.2](#)). Some degree of asymmetry is often seen, but a unilateral picture is uncommon. Acutely, the optic nerve and peripheral retina usually appear normal, although disc pallor often develops over time (see [Fig. 6.44.2B](#)).

**BOX 6.44.2 Systemic Conditions Associated With Purtscher and Purtscher-Like Retinopathy**

- Severe head, chest, or long bone trauma
- Acute pancreatitis
- Systemic lupus erythematosus (SLE)
- Fat embolism syndrome
- Thrombotic thrombocytopenic purpura (TTP)
- Hemolysis, elevated liver enzymes, low platelets (HELLP) syndrome
- Chronic renal failure
- Amniotic fluid embolism
- Scleroderma
- Dermatomyositis

**DIAGNOSIS AND ANCILLARY TESTING**

Classically, Purtscher retinopathy occurs in conjunction with severe head or chest trauma. It can also be seen after extensive long bone fractures.<sup>14</sup> For trauma-related cases, the diagnosis is apparent after fundus examination and no further evaluation is needed. However, for cases associated with a systemic medical condition, the underlying cause may not be readily apparent. Such patients may present to the ophthalmologist first if the ocular symptoms predominate.<sup>13</sup> Therefore, a Purtscher-like fundus appearance without recent trauma or known causative medical condition requires that a comprehensive medical evaluation be performed in conjunction with an internist. Fluorescein angiography shows areas of capillary dropout corresponding to the patches of retinal whitening and blocked fluorescence from intraretinal blood.<sup>13</sup> Angiographic evidence for retinal capillary nonperfusion around the fovea may be present in cases with decreased vision. Optical coherence tomography (OCT) of the Purtscher flecken demonstrates hyperreflectivity affecting the inner plexiform, inner nuclear, and outer plexiform layers consistent with deep capillary plexus ischemia.<sup>17</sup>

**SYSTEMIC ASSOCIATIONS**

Systemic diseases associated with Purtscher-like retinopathy are listed in [Box 6.44.2](#).

**PATHOLOGY**

Histopathologically, evidence exists for retinal capillary obliteration and inner retinal atrophy in areas of clinically observed retinal whitening. These findings are relatively nonspecific, being consistent with cotton-wool spots from a variety of causes.<sup>12</sup>

As noted clinically, the pathology is confined mainly to the retina posterior to the equator. Optic atrophy is typically present in varying degrees.

**TREATMENT AND COURSE**

No known treatment exists for Purtscher retinopathy. Although retinal whitening and hemorrhages disappear over weeks or months, usually no significant vision recovery occurs due to infarction of the macula or optic nerve. Macular pigmentary alterations and optic atrophy are typical late findings. Medical or surgical therapy directed at the underlying condition may help prevent additional retinal or optic nerve damage by reducing the potential for new emboli to form.

**SHAKEN BABY SYNDROME****INTRODUCTION**

In the 1970s, radiologist John Caffey proposed a whiplash-like mechanism of child abuse to explain the association of ocular and intracranial bleeding in infants who lacked external signs of head trauma.<sup>18</sup> These are now recognized as hallmark findings of shaken baby syndrome. Unfortunately, this syndrome represents a common form of child abuse that often results in significant morbidity and mortality. As the name implies, it is encountered almost exclusively in children under 2 years of age, with most being younger than 12 months.<sup>19</sup>

**Fig. 6.44.3 Shaken Baby Syndrome.** Numerous superficial retinal hemorrhages (many with white centers) in the posterior pole of an infant who had been the subject of shaking abuse. (Courtesy Dennis P. Han, MD.)

**EPIDEMIOLOGY AND PATHOGENESIS**

The age predilection is likely due to anatomical features that make the infant more likely to suffer from intracranial and intraocular bleeding as a result of shaking.<sup>18</sup> Compared to older children or adults, an infant's head is proportionately larger and heavier relative to the body and is not as well stabilized by neck muscles. The average adult is also able to generate significantly larger acceleration-deceleration forces when shaking an infant than when shaking a larger person.

Intracranial bleeding in this setting may result from shearing of the delicate vessels that bridge the cerebral cortices and venous sinuses when the brain quickly shifts within the cranium. Direct contusion may also occur. Blood, edema, and intracranial pressure elevation often result in permanent neurological damage.

The pathogenesis of the ocular hemorrhage is not well understood. Although a mechanism similar to Terson syndrome may be one explanation, it is likely that the movement of the vitreous within the globe contributes to secondary traction on the internal limiting membrane and superficial retinal vessels. Increased venous pressure transmitted to the retina (such as in Valsalva retinopathy) may also occur, especially with a firm grip on the chest with shaking or even from choking of the victim.

**OCULAR MANIFESTATIONS**

The most common ocular finding in about 85% of patients is intraocular hemorrhage in various locations—subretinal, intraretinal, preretinal (subhyaloid), and intravitreal.<sup>19–22</sup> Intraretinal and preretinal hemorrhages predominate ([Fig. 6.44.3](#)), with most concentrated in the posterior pole and usually being bilateral. In many cases, the amount of intraocular blood correlates with the degree of acute neurological damage.<sup>23,24</sup> Cotton-wool spots, white-centered hemorrhages, macular edema, papilledema, retinosis, hemorrhagic posterior vitreous detachment, macular holes, and RPE tears are less common findings.<sup>1,18,25–27</sup> After the abuse has stopped, hemorrhages and some of the other acute changes resolve within several months. Late manifestations include perimacular retinal folds, chorioretinal atrophy or scarring, optic atrophy, neovascularization, and retinal detachment.<sup>19,28–30</sup>

**DIAGNOSIS AND ANCILLARY TESTING**

The diagnosis is made when the ocular findings above are present in conjunction with certain systemic features and a history of shaking abuse. As a history of abuse may be difficult to elicit with certainty, the clinician must maintain a high index of suspicion based on the clinical findings. The hallmark nonocular sign is intracranial hemorrhage. Unlike Terson syndrome, this is usually subdural and often involves both sides of the brain.<sup>18,20,31</sup> Other findings include subarachnoid or intracerebral blood, cerebral edema, and cerebral atrophy. Elevated intracranial pressure is often present. A variety of neurological symptoms can occur, ranging from

**BOX 6.44.3 Causes of Retinal Hemorrhages in Infancy**

- Birth trauma (neonates only)
- Shaken baby syndrome
- Spontaneous intracranial hemorrhage (Terson syndrome)
- Acute hypertension
- Direct eye, head, or chest trauma (accidental or nonaccidental)
- Cardiopulmonary resuscitation
- Systemic infections and meningitis
- Viral retinitis
- Hematological disorders (e.g., malignancies, coagulopathies)
- Systemic (or retinal) vasculitis

irritability and lethargy to seizures, coma, and death. Neuroimaging is used to diagnose the intracranial pathology. Cerebrospinal fluid and subdural aspirations may be needed to confirm blood in the central nervous system.

Extracranial signs of abuse may also be evident and help confirm the diagnosis. From shaking injury alone, bruises or fractures that involve the trunk or limbs can be seen. Cervical cord hematomas have also been described and are thought to be strongly suggestive of whiplash-like injury.<sup>31</sup> However, with shaking as the only mechanism of abuse, there is often a paucity of overt extracranial findings.

OCT may show areas of focal vitreous separation in the macula, perimacular folds with vitreous attachment at the apices, epiretinal membrane, retinoschisis, lamellar or full-thickness macular hole, and even foveal detachment.<sup>32–34</sup> These findings appear to be consistent with shearing forces at the vitreoretinal interface induced by shaking. Fluorescein angiography has demonstrated areas of peripheral nonperfusion in some cases.<sup>35</sup> However, the clinical implications of this finding are unclear given that some of these patients were observed and never developed neovascularization.

**DIFFERENTIAL DIAGNOSIS**

Intraocular hemorrhages in infancy, although highly indicative of shaken baby syndrome, are not specific for child abuse as they can be seen in other conditions (Box 6.44.3).<sup>19</sup> Direct head trauma or spontaneous subarachnoid hemorrhage can result in intraocular bleeding as described before in Terson syndrome. However, some studies suggest that intraocular hemorrhage may be uncommon in children with intracranial hemorrhage from nonabusive mechanisms, such as accidental or surgical trauma.<sup>36</sup> Retinal hemorrhages can also be seen after vaginal delivery and cardiopulmonary resuscitation. Finally, several systemic conditions, including arterial hypertension, hematological disorders (e.g., leukemia), sepsis, meningitis, and vasculitis, can cause intraretinal hemorrhage.

**PATHOLOGY**

As observed clinically, the most common histopathological finding is intraocular hemorrhage with blood observed in all retinal layers, between the retina and the RPE, and in the vitreous.<sup>21,22</sup> Intraorbital optic nerve sheath hemorrhage is observed frequently and may lead to optic disc edema or optic atrophy.<sup>19,21,22</sup> Intraretinal edema, retinal folding, and RPE alterations are other not uncommon findings. Other pathological globe changes are unusual in shaken baby syndrome alone.

**TREATMENT, COURSE, AND OUTCOME**

Some degree of permanent visual loss is common, with little that can be done therapeutically to alter the visual outcome. Irreversible damage to the macula, optic nerve, and/or occipital cortex is responsible for the decreased vision.<sup>18,19,28,29</sup> Promising signs of potential for visual function are good pupillary reflexes, clear ocular media, retinal findings that are limited to intraretinal hemorrhages, and a normal optic disc.<sup>18</sup> In patients who have vitreous hemorrhage obscuring the macula, vitrectomy to clear the blood can be performed. In this setting, electroretinography should be done preoperatively, as surgery is unlikely to be beneficial if there is no significant bright flash response.<sup>18</sup> Even in cases where the visual pathway is relatively well preserved, the patient's overall function may still be very limited due to severe neurological damage.

**MISCELLANEOUS CONDITIONS****WHIPLASH INJURY**

A whiplash injury to the head in adults produces a unique ocular problem called whiplash maculopathy.<sup>37</sup> In this disorder, the patient usually reports bilateral, mild blurred vision that begins immediately after a significant head and neck flexion–extension injury. Automobile accidents with rapid deceleration are the most common cause. Visual acuity is found to be slightly decreased, rarely worse than 20/30, and ocular examination is notable only for a faint gray haze to the foveal retina accompanied by a small depression. A shallow posterior vitreous separation may also be seen. Fluorescein angiography is usually normal. OCT may demonstrate disruption of the inner segment–outer segment junction.<sup>38</sup> Within days, the vision returns to normal and the gray retinal discoloration fades, but the small foveal depression appears to persist indefinitely. Similar foveal changes can be seen after direct eye trauma with mild commotio retinae of the central macula and after sun gazing (solar retinopathy).

**FAT EMBOLISM SYNDROME**

Distinct posterior segment changes are also seen in fat embolism syndrome. A variety of systemic and ocular signs can develop within a few days of a person sustaining significant fractures of medullated bones. Retinal changes are observed in up to 60% of patients who meet the diagnostic criteria of fat embolism syndrome but in only about 5% of patients who present with long bone fractures with or without other systemic signs.<sup>14</sup>

The classic eye findings are bilateral cotton-wool spots and intraretinal hemorrhages.<sup>1,14</sup> Although the syndrome may resemble Purtscher retinopathy, the white retinal infarcts and hemorrhages are usually smaller, less numerous, and more peripheral, with most patients being asymptomatic or having minor visual complaints.<sup>12</sup>

The associated systemic manifestations of fat embolism syndrome include petechial rash, central nervous system alterations, respiratory compromise, fever, tachycardia, anemia, and elevated erythrocyte sedimentation rate. The condition is fatal in 20% of cases.<sup>1</sup> The ophthalmologist is rarely involved during the acute phase of fat embolism syndrome, as ocular symptoms are usually minimal. However, some patients notice persistent paracentral scotomata, and the ophthalmologist may be in a position to evaluate these and other ocular symptoms at some point during or after the acute phase of the syndrome.<sup>14</sup>

No treatment is currently available for ocular manifestations associated with fat embolism syndrome.

**VALSALVA RETINOPATHY**

Valsalva retinopathy occurs when increased intrathoracic or intra-abdominal pressure is transmitted to the eye, resulting in intraocular bleeding. The hemorrhage is usually unilateral or bilaterally asymmetrical and located in the macula. Subinternal limiting membrane hemorrhage is most common, but subretinal, retinal, and/or vitreous hemorrhaging may also occur. Coughing, vomiting, sneezing, straining at stool, lifting, and sexual intercourse are all possible causes. Valsalva retinopathy typically clears without sequelae. The neodymium:yttrium–aluminum–garnet and argon laser have been used to disrupt preretinal hemorrhage in selected cases to speed the clearance.<sup>39,40</sup> In most cases, laser or surgical intervention is unnecessary.

# Retinal Toxicity of Systemically Administered Drugs

6.45

Alexander L. Ringeisen, Mihai Mititelu

**Definition:** Retinal injury resulting from systemically administered drugs.

## Key Features

- Retinal pigmentary epithelial irregularities.
- Atrophy of the retina, retinal pigment epithelium, and/or choroid.
- Bullseye maculopathy.
- Crystalline deposition.
- Macular edema.

## Associated Features

- Rheumatoid arthritis.
- Collagen vascular diseases.
- Psychiatric illness.
- Acquired immunodeficiency syndrome.
- Malignancy.

## INTRODUCTION

The toxic retinopathies form a diverse group of conditions that result from retinal damage caused by systemically administered drugs. Although they are relatively rare, these conditions should be considered whenever an “unusual” retinopathy is evaluated, particularly when features of bilateral pigmentary disturbance or retinal crystal deposition are present. Adequate knowledge of systemic medication use in a patient with an unusual retinopathy can lead to prompt recognition of a toxic retinopathy. This may minimize an otherwise extensive workup and spare the patient from future exposure to the noxious agent.

## CHLOROQUINE AND HYDROXYCHLOROQUINE

Chloroquine and its derivative hydroxychloroquine (HCQ) have historically been used for prophylaxis and treatment of malaria, but currently are more commonly used to treat connective tissue diseases. The two drugs differ in their therapeutic and toxic dose ranges but can produce identical retinopathies. The exact mechanism of retinopathy remains to be elucidated, but in animal models, the ganglion cells show the earliest histological evidence of toxicity, followed by other elements of the retina (particularly the outer retina) and the retinal pigment epithelium (RPE).<sup>1</sup>

Patients with retinopathy may be asymptomatic. When symptoms do occur, the earliest complaints are usually difficulty with night vision, reading, or with other fine visual tasks caused by central or paracentral scotomas. The earliest scotomas are subtle, usually within 10° of fixation, and are more common superiorly than inferiorly to fixation.<sup>2</sup> With time, the scotomas enlarge, multiply, and may involve fixation, ultimately reducing visual acuity.

The fundus appearance may remain entirely normal even after scotomas have developed. The earliest fundus findings are irregularity in the macular pigmentation and blunting of the foveal reflex. With time, the central irregular pigmentation may become surrounded by a concentric zone of hypopigmentation, usually horizontally oval and more prominent inferior to the fovea (Fig. 6.45.1).<sup>3</sup> This paracentral depigmentation results in a bullseye maculopathy, which is a classic finding of advanced stage

HCQ toxicity. With continued exposure to the drug, or even on cessation of systemic therapy in the presence of advanced retinopathy, there may be progressive, generalized pigmentary changes. The end-stage appearance may be indistinguishable from that of a cone-rod dystrophy, with bullseye maculopathy, peripheral pigment irregularity and bone spicule formation, vascular attenuation, and optic disc pallor.

Based on improved recognition and the availability of new screening tools, the American Academy of Ophthalmology (AAO) published revised screening recommendations in 2016.<sup>4</sup> The goal of screening is to detect early toxicity prior to development of significant damage, since retinal changes are not reversible and may in fact progress after discontinuation of the drug. The overall prevalence of toxicity after 5 years of use is 75%, although it varies greatly with the duration of therapy and daily dose.<sup>5</sup> Screening should include a baseline examination for all patients starting these drugs with annual screening starting after 5 years of use. Patients with coexisting renal disease or concomitant tamoxifen use are considered at high risk of developing toxicity and may be screened more often based on the provider's clinical suspicion. The AAO recommends that all patients using HCQ keep daily dosage below 5.0 mg/kg real weight. A lower limit is advisable in patients who are at high risk as described earlier. Pre-existing maculopathy is considered a contraindication to treatment with HCQ because underlying abnormalities may mask early toxicity; therefore, these patients should try alternative therapy or have a comprehensive initial examination to establish the baseline.<sup>4</sup>

The 2016 AAO guidelines recommend baseline and follow-up screening examinations to include visual acuity testing, dilated fundus examination, spectral-domain optical coherence tomography (SD-OCT) testing, and functional assessment with Humphrey 10–2 test.<sup>4</sup> Multifocal electroretinogram (mf-ERG) and/or fundus autofluorescence (FAF) testing may be used as adjunct testing when available on an as-needed basis. SD-OCT can reveal evidence of early disruption of the parafoveal inner segment–outer segment (IS-OS) junction with thinning of the outer nuclear layer. In late stages, there is complete loss of the ellipsoid zone throughout the fovea.<sup>6</sup> Fundus autofluorescence can highlight mild increased autofluorescence in a pericentral ring around the fovea, while a complete loss of autofluorescence may be seen in severe cases.<sup>7</sup> Multifocal electroretinogram shows pericentral loss of amplitude and delayed implicit time.<sup>8</sup> Changes on Humphrey 10–2 field, even if subtle, should be evaluated by objective testing. Fundus photography, Amsler grid testing, time-domain OCT, fluorescein angiography, full-field electroretinography (ff-ERG), color vision testing, and electro-oculogram are not recommended for screening. Dilated retinal examinations should be done at each visit but are not sufficient for screening independently.

If subjective visual complaints or objective findings are suggestive of toxicity, discontinuation of the drug should be discussed with the patient and the prescribing physician. Discontinuation could lead to worsening of the underlying autoimmune disease and require use of different agents, whereas retinal changes may continue to progress chronically despite cessation of the therapeutic agent.

## SILDENAFIL

Sildenafil is an inhibitor of type-5 phosphodiesterase that is used to treat male impotence. Visual symptoms are correlated to serum concentrations of the medication and include subjective visual phenomena, including a bluish discoloration of vision and increased sensitivity to light.<sup>9</sup> Some studies have reported reversible mild reductions in ERG a- and b-wave amplitudes, increased choroidal thickness, increased error rates along the

**Fig. 6.45.1 Chloroquine and Hydroxychloroquine Maculopathy.** Spectral domain optical coherence tomography exhibits loss of ellipsoid zone and thinning of the outer retina in the parafoveal region ("flying saucer" sign) (A–B). Fundus autofluorescence shows an increased signal in the parafoveal region, which denotes abnormal retinal pigment epithelium metabolism (B). (Courtesy Mihai Mititelu, MD, MPH.)

blue–green axis in Farnsworth-Munsell 100 (FM) hue testing, and higher rod response and sensitivity shortly after ingestion.<sup>10,11</sup> Anecdotal reports of ischemic optic neuropathy, branch retinal vein occlusion, serous macular detachment, and central serous chorioretinopathy have been described. Attributing ocular changes to sildenafil is difficult, as such changes may be compounded by high exertion during sexual activity, interactions with nitrates, and other ocular comorbidities.<sup>12</sup> Current recommendations suggest sildenafil be used with caution in the setting of retinitis pigmentosa and nonischemic optic neuropathy.

## THIORIDAZINE

Thioridazine is a phenothiazine antipsychotic drug that has been used in high doses in the past. At these doses, a subacute, dramatic form of retinopathy could appear<sup>13,14</sup> with extensive geographic areas of depigmentation, loss of choriocapillaris, and optic atrophy. At the lower doses (<800 mg/d) used today, this dramatic type of retinopathy rarely, if ever, occurs.

A variant referred to as nummular retinopathy has been described in patients taking chronic doses of thioridazine. These patients are much less likely to have symptoms. Multiple large round areas of depigmentation and atrophy develop posterior to the equator, with relative sparing of the macula (Fig. 6.45.2). Over time, the areas of atrophy may enlarge and become confluent. Fluorescein angiography demonstrates loss of pigment epithelium and choriocapillaris within the areas of depigmentation.<sup>15,16</sup> Visual field changes are nonspecific, but most characteristically show paracentral scotomas or ring scotomas.

The manufacturers' current recommendation is that the dose be titrated to a minimal effective dose of 300 mg/day or less, with an absolute maximum of 800 mg/day for limited periods. Cases of retinopathy among patients treated according to these guidelines remain rare.

## NIACIN

Niacin (nicotinic acid, vitamin B<sub>6</sub>) is used at pharmacological doses to lower serum cholesterol, and rarely maculopathy may develop in patients taking 1.5 g or more daily.

Affected patients develop central visual changes weeks or months after the initial administration of the drug. Reduction in visual acuity is usually mild to moderate.<sup>17,18</sup> Patients develop a bilateral maculopathy that has the clinical appearance of cystoid macular edema, but there is no dye leakage or accumulation with fluorescein angiography. OCT reveals the presence of cystoid spaces in the inner nuclear and outer plexiform layers (Fig. 6.45.3).<sup>19</sup> The subjective and objective findings improve after the medication is withdrawn, but if left untreated, chronic macular edema may lead to retinal and retinal pigment atrophy causing permanent vision loss.

## CANTHAXANTHINE

Canthaxanthine is a carotenoid drug that, when taken orally, causes bronzing of the skin. Although it has been used for treatment of certain dermatological disorders such as vitiligo, its main use has been as an artificial tanning agent. The risk of retinopathy is dose related. At cumulative doses

of greater than 30 g, the majority of patients are found to have retinopathy. Patients who have canthaxanthine retinopathy are usually asymptomatic. The fundus appearance is bilateral wreath formation of highly refractile yellow crystals found in the inner retinal layers that surround the fovea (Fig. 6.45.4).<sup>20</sup>

Although the patients are usually asymptomatic, central perimetry demonstrates reduced sensitivity in patients who have retinopathy. After cessation of drug therapy, visual field testing may return to normal as the number of visible crystals decreases slowly over many years.<sup>21</sup>

**Fig. 6.45.2 Thioridazine Retinopathy Associated With Chronic Use (Nummular Retinopathy).** (From Weinberg DV, D'Amico DJ. Retinal toxicity of systemic drugs. In: Albert DM, Jakobiec FA, editors. Principles and practice of ophthalmology. Philadelphia: WB Saunders; 1994. p. 1042–50.)

## TAMOXIFEN

Tamoxifen is a nonsteroidal estrogen antagonist that is used in the treatment of breast cancer. Retinopathy was first described among women treated with more than 180 mg/day for longer than a year.<sup>22</sup> These patients usually had a symptomatic decrease in vision and characteristic fundus findings were small, white, refractile deposits in the inner retina, particularly in the perimacular area. Associated pigmentary irregularity occurred (Fig. 6.45.5).<sup>23</sup>

Currently, the drug is used at much lower doses, typically 20 mg/day. Fluorescein angiography demonstrates window defects and/or cystoid macular edema. OCT studies have revealed a foveolar cystoid space and loss of photoreceptors without macular thickening (see Fig. 6.45.5).<sup>24,25</sup> Many of the cases of low-dose tamoxifen retinopathy have been asymptomatic, but mild to moderate reduction of visual acuity has been reported in others. Conflicting data exist in the literature as to the incidence and significance of retinopathy in asymptomatic patients.<sup>26–30</sup> Although mild crystal deposition with or without macular edema may be possible with low doses, it is probably uncommon. This is supported by the large number of patients treated with this drug and the relative paucity of well-documented cases in the literature. There is lack of consensus in the literature as to whether routine screening of asymptomatic patients using lower doses of tamoxifen is necessary. Cessation of medication should be considered if visual function is affected but only after discussion with the patient's oncologist.

## FINGOLIMOD

Fingolimod is a US Food and Drug Administration (FDA)–approved oral drug for relapsing multiple sclerosis<sup>31</sup> and is associated with macular edema in a subset of patients. Incidence of macular edema is about 0.2% with 0.5 mg/d dose and increases with higher doses and in the presence of comorbidities such as pre-existing uveitis and diabetes. Patients may complain of blurred vision or have minimal or no symptoms. OCT reveals intraretinal cystic spaces, and dye leakage is seen on fluorescein angiography. According to the prescribing information, patients starting fingolimod should have a comprehensive baseline examination followed by repeat examination after 3 or 4 months. If macular edema develops, discontinuation of fingolimod should be considered in consultation with

**Fig. 6.45.3 Spectral-Domain Optical Coherence Tomography Demonstrating Cystoid Spaces in the Outer and Inner Nuclear Layers and Possibly the Ganglion Cell Layer in the Right Eye and in the Inner Nuclear Layer in the Left Eye.** (From Courtney RJ and Singh RP. Spectral domain optical coherence tomography features in niacin maculopathy. Eye [Lond] 2014;28:629–32. Figure 2.)

the neurologist.<sup>32</sup> Should the patient and prescribing physician wish to continue fingolimod, treatment of the macular edema has been successfully reported using topical nonsteroidal anti-inflammatory drugs and sub-Tenon's triamcinolone.<sup>33,34</sup>

## PACLITAXEL

Paclitaxel (in both its free and albumin bound versions) and docetaxel are related drugs used as chemotherapeutic agents. They can cause cystoid macular edema without dye leakage on fluorescein angiography (Fig. 6.45.6). It is believed that the macular edema occurs secondary to damage to Müller cells.<sup>35</sup> Discontinuation of the medication (and replacement with a different chemotherapeutic agent) usually leads to resolution of the cystoid macular edema (CME).<sup>36</sup>

## DEFEROXAMINE

Deferoxamine mesylate is a chelating agent used to reduce iron levels in patients with transfusion-dependent anemia and to treat aluminum toxicity in patients receiving chronic renal dialysis. The onset of visual symptoms

from deferoxamine toxicity may be relatively acute or occur after long exposure. The incidence may be higher in dialysis patients and in older individuals.<sup>37</sup> Patients usually complain of blurred vision, nyctalopia, color vision abnormalities, or visual field restriction. At the time of onset, the fundus may appear normal or subtle pigment mottling may be found. The spectrum of changes varies widely and may include RPE window defects, bullseye lesions, vitelliform maculopathy, and late hyperfluorescence of the macula.<sup>38,39</sup> Color vision is frequently abnormal, typically with a tritan dyschromatopsia. Visual field testing usually shows central or cecentral scotomas and, less commonly, peripheral restriction. Electroretinography may show decreased amplitude and prolonged implicit times. Visually evoked potentials may also show low voltage and delayed conduction times. Where available, fundus autofluorescence is an effective method for screening patients at risk for deferoxamine retinal toxicity.<sup>40</sup> If deferoxamine is withdrawn promptly, partial or complete functional recovery is usually seen. The maculopathy may progress, however, and develop into coarse macular pigmentary changes and occasionally peripheral pigmentary clumping as well.

## DIDANOSINE

Didanosine (2',3'-dideoxyinosine) is an antiretroviral drug used for the treatment of human immunodeficiency virus infection. A peripheral retinal degeneration has been observed in children and adults treated with this drug.<sup>41,42</sup> Fundus findings consist of small, sharply demarcated areas of retinal and RPE atrophy around the midperiphery. This degeneration may progress with continued exposure to the drug. ERG may exhibit signs of rod and cone dysfunction. Central visual acuity is usually preserved with restriction of peripheral visual field.<sup>41,43,44</sup> Cessation of the medication should be considered once retinopathy is detected.<sup>42</sup>

## CLOFAZIMINE

Clofazimine is an iminophenazine dye with antimycobacterial and anti-inflammatory activity. Retinal toxicity in the form of a bullseye maculopathy has been reported in patients who were given clofazimine for treatment of *Mycobacterium avium* complex infections associated with acquired immunodeficiency syndrome. In contrast to other bullseye maculopathies, the pigment changes in these patients were more extensive and extended outside the major vascular arcades.<sup>45,46</sup>

## THIAZOLIDINEDIONES

Thiazolidinediones are oral antidiabetic agents that include rosiglitazone and pioglitazone. They are known to cause excess fluid retention in some patients. A case series suggested a possible link between use of these

**Fig. 6.45.4 Canthaxanthine Retinopathy.** Large yellow crystals are distributed in a prominent macular ring. (From Weinberg DV, D'Amico DJ. Retinal toxicity of systemic drugs. In: Albert DM, Jakobiec FA, editors. Principles and practice of ophthalmology. Philadelphia: WB Saunders; 1994. p. 1042–50.)

**Fig. 6.45.5 Tamoxifen Retinopathy. Pseudocystic Foveal Cavitation in Tamoxifen Retinopathy.** (Top left) Color fundus photograph of the right eye demonstrates yellow spots in the posterior pole, (top middle) corresponding to punctate hyperautofluorescent foci on autofluorescence imaging. There is an absence of normal hypoautofluorescence in the fovea. (Top right) Spectral-domain optical coherence tomography imaging demonstrates foveal cavitory spaces. (Bottom) Similar findings are present in the left eye, with more pronounced cavitation. (From Doshi RR, Fortun JA, Kim BT. Pseudocystic foveal cavitation in tamoxifen retinopathy. Am J Ophthalmol 2014;157:1291–1298.e3. Figure 1.)

**Fig. 6.45.6 Paclitaxel Toxicity.** Paclitaxel causes cystoid macular edema evident on optical coherence tomography (A–B) which resolved 7 weeks after discontinuation of paclitaxel therapy (C–D). Initial presentation shows cystoid macular edema with or without dye leakage on fluorescein angiography (E–H). (From Padrón Pérez N, Rubio Caso MJ, Arias Barquet L, et al. Bilateral cystoid macular edema in a patient with taxane-based chemotherapy. *Can J Ophthalmol* 2013;48:e3–e4. Figure 1.)

drugs and diabetic macular edema, especially in patients with generalized fluid retention. In such cases, cessation of medication leads to prompt resolution of diabetic macular edema.<sup>47</sup> Later, more robust studies have been mixed in identifying a causal relationship between thiazolidinediones and the development of macular edema.<sup>48,49</sup>

## IMATINIB

Imatinib is a tyrosine kinase inhibitor that is used in the treatment of chronic myelogenous leukemia. It leads to generalized fluid retention throughout the body and may cause macular edema.<sup>50–52</sup> Cessation of drug therapy and replacement with different chemotherapeutic drug typically results in resolution of macular edema with subsequent vision improvement.

## MITOGEN-ACTIVATED PROTEIN KINASE INHIBITORS AND IMMUNE CHECKPOINT INHIBITORS

Oncological agents such as mitogen-activated protein kinase (MEK) inhibitors and immune checkpoint inhibitors target extracellular signaling and have become common in the treatment of cancers, including cutaneous

metastatic melanoma, non–small-cell lung cancer, and lymphoma among others. MEK inhibitors (trametinib, cobimetinib) and immune checkpoint inhibitors (ipilimumab, pembrolizumab) have been implicated in cases of bilateral serous retinal detachments with or without uveitis. Specifically, central serous-like chorioretinopathy has been reported with use of various MEK inhibitors (presumably due to toxicity to the RPE), whereas rare cases of Vogt–Koyanagi–Harada–like syndrome have been described in genetically predisposed patients receiving immune checkpoint inhibitors. Discontinuation of the chemotherapeutic agent is associated with spontaneous resolution of the serous detachments.<sup>53–55</sup>

# Anatomy of the Uvea

Monica Evans

## 7.1

**Definition:** The uvea is a pigmented, vascular structure consisting of the iris, ciliary body, and choroid.

### Key Feature

- Supplies blood to most of the eye from anterior and posterior ciliary branches of the ophthalmic artery.

### Associated Features

- Produces aqueous humor in the ciliary processes.
- Controls near accommodation by contraction of ciliary muscles, which relax the zonular fibers to the lens.
- Increases aqueous outflow by contraction of ciliary muscles, which open the trabecular meshwork.

## INTRODUCTION

The uveal tract is the vascular coat of the eye, lying between the sclera and the neuroepithelium. It consists of the iris, ciliary body, and choroid. The former represents the anterior part, the latter the posterior part, and the ciliary body forms the middle part. The uvea contains nerves, supporting connective tissue, and a variable number of melanocytes that are responsible for its distinctive color. The uvea is supplied anteriorly by long posterior ciliary arteries and the anterior ciliary arteries. Posteriorly the uvea is supplied by several posterior ciliary arteries that enter the choroid around the optic nerve.

The choroidal vasculature is responsible for approximately 80% of blood supplies in the eye. A unique feature about the human retina is the presence of two blood–retina barriers: the inner and outer blood–retina barriers that are formed by tight junctions between adjacent endothelial or retinal pigment epithelial cells. The outer blood–retina barrier separates the neural retina from a network of fenestrated vessels called choriocapillaris, which is the major blood supplier for the neural retina. This barrier plays many essential roles in the maintenance of normal physiological processes in the retina, through the transport of nutrients, water, and ions and the removal of metabolic wastes.<sup>1</sup>

Pathological changes involving the uvea primarily include vascular, inflammatory, and neoplastic diseases. Both primary and metastatic tumors are found in the iris, ciliary body, and choroid. Inflammatory changes are clinically recognized as uveitis and are divided into anterior, posterior, intermediate, and pan uveitis.

## IRIS

The iris forms a diaphragm in front of the crystalline lens. The iris controls the amount of light transmitted into the eye by changes in the pupillary size. The vascular supply to the iris originates in the anterior and long posterior ciliary arteries. Histologically, the iris is made up of three layers:

- An anterior layer is composed of fibroblasts, melanocytes, and collagen, and its anterior surface is folded into many ridges and crypts.
- A middle stromal layer contains fibroblasts, melanocytes, and collagen.
- A posterior layer is composed of the dilator muscle and pigment epithelium (Fig. 7.1.1).

The stroma, or middle layer, makes up the bulk of the iris and contains blood vessels, nerves, melanocytes, and clump cells in a loose extracellular

**Fig. 7.1.1 Normal Iris. Pupillary zone.** Note the sphincter muscle.

matrix of collagen and mucopolysaccharides.<sup>2</sup> The iris color is determined by the number and degree of melanin granules in the superficial stromal melanocytes.<sup>3</sup> Uveal melanosomes originating in the iridal stroma contain both black (eumelanin) and red (pheomelanin) pigment. Eumelanin/pheomelanin ratio varies with iris color, with lower ratios being observed for lighter color (hazel, blue) irides.<sup>4</sup>

Unlike the anterior surface, the posterior epithelium is velvety smooth and uniform. It consists of two layers of densely pigmented cells, which are arranged apex to apex.<sup>5</sup>

The dilator muscle of the pupil extends from the region of the sphincter muscle to the base of the iris and is located in the posterior portion of the iris. The sphincter muscle is located in the posterior iris stroma in the pupillary zone and consists of a circular band of smooth muscle fibers (Fig. 7.1.2). The dilator muscle is innervated by parasympathetic nerves and the sphincter muscle by the sympathetic nervous system.

## CILIARY BODY

The ciliary body extends from the base of the iris and becomes continuous with the choroid at the ora serrata. It is approximately 6–6.5 mm in anteroposterior dimension. It consists of an anterior portion called the pars plicata and a posterior portion called the pars plana. The pars plicata contains approximately 70 finger-like projections called ciliary processes, which are covered by the ciliary body epithelium (Fig. 7.1.3). The pars plicata is the flat part of the ciliary body and ends at the ora serrata. The ciliary processes are thin and finger-like in children (Fig. 7.1.4). With age they become thickened and reveal hyalinization of the stroma (Fig. 7.1.5). The stroma of these areas is filled with fibrous connective tissue, rich vascular networks, melanocytes, and bundles of smooth muscle.

The smooth muscle of the ciliary body can be divided into three groups of fibers: the outer longitudinal portion that attaches anteriorly to the scleral spur and trabecular meshwork fibers, a middle oblique portion, and the inner circular portion.<sup>6</sup> Accommodation is the result of a parasympathetic stimulus that is followed by contraction of the ciliary muscle, which decreases the zonular tension on the crystalline lens. This allows the lens

**Fig. 7.1.5** Ciliary Body of an Adult, Revealing Marked Hyalinization of the Stroma.

to move forward and assume a more spherical shape, increasing the dioptric power of the eye.

The innermost part of both pars plana and pars plicata is covered by a bilayer epithelium: the outer pigmented epithelium cells and the inner nonpigmented cells. The cells of these two layers are arranged apex to apex with tight junctions between them. The zonula occludens near the apices of the nonpigmented epithelial cells form the blood–aqueous barrier. The principal source of aqueous humor is the nonpigmented ciliary epithelium of the pars plicata. Production of the vitreous mucopolysaccharide has been attributed to the nonpigmented ciliary epithelium of the pars plana.

## CHOROID

The choroid is the principal vascular and pigmented tissue that forms the middle coat of the posterior part of the eye. It extends from the ora serrata to the optic nerve.<sup>7</sup> The choroid is the most vascular tissue in the eye, and it has been implicated in the pathophysiology of a variety of ocular diseases.<sup>8</sup> It is attached to the sclera by connective tissue strands and especially posteriorly by numerous blood vessels and nerves that enter the choroid from the sclera. Small amounts of choroidal tissue may extend into the scleral canals through which ciliary vessels and nerves enter the eye. It varies in thickness from 0.1 mm anteriorly to 0.22 mm posteriorly. Choroidal thickness maps using a spectral-domain optical coherence tomographic instrument show that thinner choroidal area spreads around the optic disc and the peripapillary choroid increases in thickness the farther it is away from the optic nerve. The peripapillary choroid in the inferior quadrant is significantly thinner compared with all other quadrants.<sup>9,10</sup>

Histologically, the choroid reveals four layers: the lamina fusca, the stroma, the choriocapillaris, and Bruch's membrane. Bruch's membrane can be divided into five components: the basement membrane of the retinal pigment epithelium, an inner collagenous zone, an elastic layer, the outer collagenous zone, and the basement membrane of the endothelium of the choriocapillaris. The choriocapillaris, a highly vascularized layer, is the capillary layer of the choroid and provides nutrition to the retinal pigment epithelium and outer retinal layers (photoreceptor cell and outer plexiform layers and the outer aspect of the inner nuclear layer). It appears to have a finely spotted appearance and to be arranged in polygonal structures that might be associated with clusters of choriocapillaris lobules of 200- to 250- $\mu$ m diameter and approximately 20- $\mu$ m thickness with a central arteriolar feeder and an array of draining venuoles.<sup>11,12</sup> The endothelial cells lining the choriocapillaris are fenestrated and are joined by gap junctions. The stroma of the choroid contains larger arteries and veins. These vessels are not fenestrated. The lamina fusca is the transition zone between sclera and choroid. It consists of a delicate meshwork of elastic fibers, fibrocytes, and melanocytes, traversed by long posterior ciliary nerves and vessels.

There are various studies that can be used to visualize the choroid vascular structures. Fluorescein angiography (FA) and indocyanine green angiography (ICGA) are both invasive tests that require intravenous administration of dye and imaging for 10–30 minutes. Fluorescein is typically used to visualize the retinal vasculature, whereas ICGA is used to see the choroidal vasculature.<sup>13</sup> Optical coherence tomography angiography (OCTA) is a new noninvasive imaging technique that employs motion contrast imaging to high-resolution volumetric blood flow information,

generating angiographic images in a matter of seconds. OCTA can show images from the internal limiting membrane (ILM) to the choroid to visualize the individual vascular plexus and segment the inner retina, outer retina, choriocapillaris, or other area of interest.<sup>8</sup>

# Mechanisms of Uveitis

Igal Gery, Chi-Chao Chan

# 7.2

**Definition:** Uveitis represents a complex intraocular inflammatory process that can involve not only the uveal tract but also the retina, vitreous, optic nerve, cornea, and sclera.

## Key Feature

- Inflammation, including leukocytic infiltration, and exudate in the anterior chamber and/or vitreous, as well as inflammation in the uvea and retina.

## Associated Features

- Idiopathic in many instances.
- When an underlying cause is identified, the causative agents and/or mechanisms include infection, trauma, and autoimmunity.

## INTRODUCTION

The term uveitis is used for a group of conditions in which inflammation affects various components of the uveal tract (i.e., the iris, ciliary body, and choroid). In addition, diseases in which adjacent uveal tissues such as the retina and vitreous are affected are also often included under the term uveitis. Some uveitic conditions are caused by infection, whereas all other noninfectious uveitis are assumed to be initiated by immune processes, in particular autoimmunity.<sup>1</sup>

The human immune response has been extensively investigated in the last four decades. This chapter focuses on issues of the immune response related mostly to ocular inflammation; additional information on the immune system is available in numerous reviews and books.<sup>2</sup> The physiological function of the immune system is defense against infection, but in certain situations immune responses are harmful, causing pathological outcomes such as allergy or autoimmune disease. The major outcome of both physiological and pathological immune responses is inflammation, with ensuing local tissue damage that is detrimental to the nondividing cells (the retina and optic nerve) of the vision process. Therefore, this chapter emphasizes posterior uveitis.

## INNATE AND ADAPTIVE IMMUNITIES

Defense against infection is mediated by two systems. There is an early innate immunity that clears the infection or keeps it in check until the second system, antigen-specific adaptive immunity, develops. The two systems consist of both cellular and humoral components. The cellular component of the innate immunity includes several populations of phagocytes, natural killer (NK) cells, and NKT cells.<sup>3</sup> The molecules that participate in innate immunity include components of the complement cascade, the acute phase response proteins, and numerous cytokines and chemokines. In addition to directly confronting infective agents, phagocytic cells of the innate immunity system provide specific stimuli to the adaptive immunity, mainly by the release of proinflammatory cytokines such as interleukin (IL)-1 and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), and by triggering antigen-presenting cells (APCs) via their toll-like receptors (TLRs). TLRs, which are located mainly on phagocytes, detect microbial products and trigger the expression of genes, in particular those of proinflammatory cytokines, such as interferons, and chemokines and costimulatory molecules.

The system of adaptive immunity differs from that of innate immunity by being antigen specific and including a memory component. The

cellular component of the adaptive immunity consists of two families of lymphocytes, B and T cells. B cells respond by producing specific antibodies, whereas T cells respond by acquiring the features of effector cells, then either produce cytokines that activate other cells or become cytotoxic, capable of lysing cells that express the target antigen.

All components of both the innate and adaptive immune systems are involved in the pathogenic processes of ocular inflammation.

## CELLS OF THE IMMUNE SYSTEM

### Nonlymphocytic Leukocytes

Nonlymphocytic leukocytes are derived from bone marrow myeloid cells. The primary function of these leukocytes is to identify, ingest, and destroy microbes. These cells belong to two major families, the granular and non-granular leukocytes. The granulocytes are characterized by the presence of granules in their cytoplasm and are divided into three subpopulations: neutrophils (polymorphonuclear leukocyte, PMN), basophils, and eosinophils. PMNs are crucial in the defense against bacterial infection and are the first cells to be recruited into infected tissues. In addition, these granulocytes, mainly PMNs, are the hallmark of acute inflammation. These cells are often found in uveitic conditions such as Behçet's disease and other acute uveitides and are a major component in many animal models of uveitis.<sup>4</sup> Basophils and eosinophils also play specific roles in the allergic reaction,<sup>5</sup> whereas eosinophils specifically participate in the response against helminths.<sup>6</sup>

The agranulocytes include macrophages, their circulating precursors, the monocytes, and the dendritic cells. Agranulocytes play central roles in both innate and adaptive immunity. Macrophages are found in normal tissues and are major participants in inflammation, in particular of the chronic type. These cells are also capable of forming "giant cells" following fusion of many macrophages that phagocytosed foreign bodies or insoluble antigens. Giant cells characterize certain chronic forms of uveitis (granulomatous uveitis) such as Vogt-Koyanagi-Harada (VKH) disease, sympathetic ophthalmia, or sarcoidosis.<sup>4</sup> A major function of macrophages is to serve as APCs (detailed later).

Another population of cells specific to the eye and the brain are the microglia. These bone marrow-derived cells resemble macrophages in many aspects, and their main function is assumed to be removal of apoptotic cells, both during development and following apoptotic events such as light damage or retinal degeneration due to genetic defects.<sup>7</sup>

### B Cells

The main function of this population of lymphocytes is to produce antibodies, the major humoral component of adaptive immunity. Antibodies play minor roles in the pathogenesis of immune-mediated uveitis except for autoimmune retinopathy<sup>8</sup> and phacoanaphylactic endophthalmitis.<sup>9</sup> B cells are also capable of presenting antigens to T cells, and in this capacity they may play an important role in the process of sensitization and/or activation of pathogenic T cells. Certain B cells may also function in regulation of immune responses and are accordingly named B-regulatory (Breg) cells.<sup>10</sup>

### T Cells

The population of T cells comprises several subsets of lymphocytes that mature in the thymus and are responsible for four major functions of the antigen-specific immune response:

- Mediation of cellular or delayed-type hypersensitivity.
- T-cell cytotoxicity.

- Immunoregulation.
- Providing help to antibody-producing B cells.

All T cells express a receptor, TCR, which determines their antigen specificity. The two major subsets of T cells are designated according to their function as helper (Th) and cytotoxic (Tc or CTL) cells and are identified by expressing markers designated CD4 or CD8, respectively. These two major populations are further divided into subpopulations according to their function and the cytokines they produce.

Five subpopulations of Th cells have been identified so far, Th1, Th2, Th9, Th17, Th22, classified mainly according to the signature cytokines they produce and their function in the immune response.<sup>11</sup> Of particular importance are the Th1 and Th17 subpopulations, with the signature cytokines interferon (IFN)- $\gamma$  and interleukin (IL)-17, respectively. Th1 and Th17 are involved in protection against microbial and parasitic infection and are also responsible for initiation of pathogenic autoimmune diseases in various organs, including the eye.<sup>11</sup> In addition to subsets of T cells with effluent functions, data collected in recent years have revealed that Th cells also perform immunoregulatory functions and are responsible to a large extent for the process of peripheral tolerance (see later). The data indicate that different populations of T cells are involved in this activity, with the majority of these cells carrying the surface markers of CD4 and CD25. Another marker, the transcription factor FoxP3, was found to be closely related to the regulatory activity of these cells.<sup>12</sup>

## Mast Cells

Mast cells are bone marrow-derived cells that reside in many tissues, including those of the eye, and perform multiple functions, such as being the major cells involved in the allergy reaction. Mediators released by mast cells induce leakage of blood vessels, and thus mast cells are assumed to promote the uveitogenic process.<sup>13</sup>

## NK and NK T Cells

The large population of NK cells is a component of the innate immunity system, and their function is to kill cells that acquire abnormal antigenicity mainly due to viral infection. The killing capacity of NK cells is enhanced by innate immunity molecules, IFN- $\alpha$ , and IFN- $\beta$ .

NK T (NKT) cells are a unique T-lymphocyte sublineage that expresses surface markers of both NK and T cells.<sup>3</sup> The function of these cells is complex, as they can promote or suppress immune responses, including those involved in the development of experimental autoimmune uveitis (EAU).<sup>14</sup>

## Antigen-Presenting Cells

APCs play a major role in the immune system by enabling T cells to recognize their target antigen. Since TCRs recognize only short peptides, in combination with major histocompatibility complex (MHC) molecules, APCs are essential for cleaving the antigenic protein and providing its peptides in complex with MHC molecules. The populations of APCs include dendritic cells, macrophages, and B cells. Enhanced expression of MHC is shown in ocular resident cells in eyes with uveitis.<sup>15</sup>

## MOLECULES OF THE IMMUNE SYSTEM INVOLVED IN UVEITIS

Immune responses are mediated by molecules that are released by or expressed on the cellular surface. These are detailed in the subsections that follow.

### Antibodies

Antibodies are produced and released by B cells and mediate immunopathogenic processes of types I, II, and III (see later). With the exception of a rare ocular condition, autoimmune retinopathy and phacoanaphylactic endophthalmitis,<sup>8,9</sup> antibodies seem to play minor roles in the pathogenesis of uveitis.

### Cytokines

Cytokines are proteins that are produced by lymphoid and a variety of other cells. These molecules are responsible for communication between

cells of the immune system and are the principal mediators of inflammation and immune reactions.<sup>2</sup> Most known cytokines are designated by the term interleukin (IL). As of 2017, there are 41 well-defined ILs, and the list will certainly get longer.

Analysis of cytokines in mouse eyes with immune-mediated inflammation revealed that the great majority of the 34 tested cytokines were upregulated at the peak of disease, indicating the involvement of a large number of molecules in the pathogenic process.<sup>16</sup> Cytokines, in particular IFN- $\gamma$ , IL-17, TNF- $\alpha$ , and IL-1, play pivotal roles in the inflammatory process by affecting a large spectrum of cells that express the corresponding specific receptors. Thus they initiate a complex sequence of events that includes activation of the same and other cells and the production of numerous additional molecules, including other cytokines, chemokines, and adhesion molecules. In contrast to these proinflammatory cytokines, there are cytokines, in particular IL-4, IL-10, IL-35, and TGF- $\beta$ , that may exert an opposite effect (i.e., inhibition of immune responses).

## Chemokines and Chemokine Receptors

Chemokines are a family of low-molecular-weight (8–10 kDa) cytokines that exert the capacity of chemoattraction for cells that express receptors with specificity toward the corresponding chemokines. Together these two families of molecules are responsible for the cell migration of the inflammatory process. Chemokines are divided into four groups, on the basis of the number and location of their N-terminal cysteine residues. Chemokine receptors are divided according to their specific interaction with chemokines of one of the four subfamilies. The receptors exhibit overlapping specificity for chemokines of the same subfamily, however. All receptors act by coupling to G-proteins that activate enzymes, including those that stimulate cellular locomotion. Numerous chemokines and chemokine receptors participate in the uveitic process.<sup>16,17</sup>

## Adhesion Molecules

These molecules are expressed on the surface of cells of the immune system and other cells and are responsible for promoting adhesive interactions with other cells or with the extracellular matrix. This family of molecules, which includes the selectins, integrins, and members of the immunoglobulin superfamily, is crucial for cell migration and activation during the inflammatory process (see later). Enhanced expression of adhesion molecules has been demonstrated in the resident cells of uveitic eyes.<sup>18</sup>

## Other Molecules

Other molecules that participate in the immunopathogenic process of uveitis include mainly members of the complement cascade. Certain members of this group are chemotactic for leukocytes and were found to play major roles in the development of experimental uveitis.<sup>19</sup>

The involvement of certain molecules in inflammatory processes in the eye is detailed later. An increasing number of these molecules have become targets for the treatment of uveitis.

## TOLERANCE AND AUTOIMMUNITY

Apart from protection against invading pathogens, the immune system is required to avoid developing pathogenic immune response against self-antigens (i.e., autoimmunity). In normal conditions, this requirement is well met by using multiple mechanisms that together prevent development of pathogenic autoimmunity. Disease may develop, however, when one or more of these mechanisms fail. These mechanisms include central and peripheral tolerance, anergy, immunoregulation, and ignorance.

### Central Tolerance

Central tolerance is the major mechanism for prevention of autoimmunity. This process takes place in the thymus, the organ in which immature lymphocytes that originated in the bone marrow undergo two selection processes before migrating into the periphery. Firstly, thymocytes are positively selected in the thymic cortex, according to their capacity to interact with self MHC molecules. Next, the positively selected lymphocytes migrate into the thymic medulla, where self-antigens are expressed, and induce apoptosis in thymocytes with high affinity toward these autoantigens. The negative selection process is extremely effective, and trace amounts of tissue-specific antigens were found to eliminate large numbers of thymocytes specific to these antigens.<sup>20,21</sup>

It is of note that uveitogenic antigens can be found in thymi of both human donors and mice.<sup>20,22</sup> Importantly, the level of expression of individual uveitogenic antigens in the thymus of mice of different strains was found to be inversely related to susceptibility to induction of EAU by these antigens.<sup>23</sup> These observations—and the finding that the level of thymic expression of tested retinal antigens varied among individual human donors<sup>22</sup>—suggest, therefore, that susceptibility to uveitis is determined at least in part by the level of thymic expression of uveitogenic antigens.

Negative selection is, however, an incomplete process, and lymphocytes with low affinity toward autoantigens do escape deletion.<sup>24</sup> Several mechanisms are in place to prevent these cells from initiating pathogenic autoimmunity. These are described in the following subsections.

## Peripheral Tolerance

Peripheral tolerance is an incompletely defined process and includes at least three different mechanisms:

- Elimination of autoantigen-specific lymphocytes by apoptosis following exposure to high levels of the target protein.
- Induction of anergy in the self-specific lymphocytes following exposure to the antigen in the absence of costimulation.
- Suppression by T-regulatory cells.

The existence, features, and activity of T-regulatory cells have been well studied in recent years (see earlier) and their capacity to inhibit autoimmune uveitis has been established in the animal model of EAU.<sup>25</sup>

## Ignorance

This poorly studied mechanism probably plays a major role in preventing pathogenic autoimmunity against partially sequestered antigens such as most ocular proteins. Lymphocytes specific against ocular- and other organ-specific antigens are readily found in normal humans,<sup>24</sup> and immune ignorance is assumed to be responsible at least in part for the absence of pathogenic autoimmunity in these cases. The generally accepted explanation for the inactivity of self-specific lymphocytes is their naïve status.

## MECHANISMS THAT TRIGGER AND PROMOTE UVEITOGENIC PROCESSES

Uveitis develops in only a small proportion of humans, and accumulating data have identified several mechanisms that trigger and promote the development of this pathogenic process. These mechanisms include genetic makeup and environmental factors such as trauma and microbial infection.

## Genetic Background

The possible involvement of genetic factors in the pathogenesis of uveitis has been indicated in studies with twins, familial aggregation, and in particular by the associations between several uveitic conditions and certain human leukocyte antigen (HLA) alleles.<sup>22,26</sup> The observations in humans were confirmed in studies with experimental animals in which associations were found between the susceptibility to the induction of EAU and the genetic makeup of the animal. The data with well-defined mouse strains show that the susceptibility to EAU is affected by both MHC and non-MHC genes.<sup>27</sup>

## Trauma

The role of trauma as the trigger mechanism for development of pathogenic autoimmunity in the eye is indicated by two severe inflammatory eye diseases that develop following trauma, namely, sympathetic ophthalmia<sup>9</sup> and phacoanaphylactic endophthalmitis.<sup>28</sup> The original notion about the pathogenesis of these conditions had been that the damage releases sequestered antigens from the uvea or lens, respectively, and initiates specific autoimmune responses that selectively affect these tissues. More recent studies have suggested, however, that release of sequestered antigen by itself does not trigger an immune response and that additional mechanisms are involved in the initiation of the immunopathogenic response. These mechanisms include microbial contamination that often accompanies the trauma and the accumulation of necrotic products at the site. Necrotic cells promote immunopathogenicity by stimulating danger signals and proinflammatory processes.<sup>29</sup> It is of note that in contrast to

the proinflammatory activity of cells dying by necrosis, cells undergoing apoptosis stimulate anti-inflammatory activity.<sup>29</sup>

## Microbial Infection

Microbial infection is assumed to trigger pathogenic autoimmunity by two different mechanisms: molecular mimicry and non-antigen-specific stimulation of the immune response by microbial molecules.

The notion of molecular mimicry being a trigger for autoimmunity was proposed following the finding of identity between short stretches of sequence of uveitogenic antigens, such as arrestin (S-antigen), and certain microbial products.<sup>30</sup> Furthermore, immunization of experimental animals with the microbial molecules induced inflammatory changes similar to those induced by the ocular antigen.<sup>30</sup> It is possible, therefore, that effector cells specific against microbial products could initiate pathogenic responses following recognition of the tissue antigens that cross-react with the microbial components.<sup>31</sup> This notion was further promoted by the finding that naïve lymphocytes, specific against a retinal antigen, are activated by components of the intestinal flora to acquire pathogenicity and induce uveitic changes in the mouse eyes.<sup>32</sup> Moreover, the experimental system used in this study indicated that the intestinal flora is crucial for development of spontaneous EAU in these mice.<sup>32</sup>

Another likely mechanism for triggering pathogenic autoimmunity is via stimulation of the innate immunity by microbial products that activate the immune response through the TLR system. Numerous microbial molecules, such as endotoxin, bacterial DNA, or viral RNA, are potent ligands for TLRs that are expressed on macrophages and other APCs.<sup>33,34</sup> The activity of these TLR-ligands is the basis for their “adjuvant” capacity.

As all mechanisms mentioned here are capable of promoting pathogenic autoimmunity, it seems likely that uveitic conditions develop as a result of synergy between the different mechanisms.

## MECHANISMS OF INFLAMMATION

### Types of Immunopathogenic Processes

Disease-inducing immunological processes have been classified into four types, according to the pathogenic mechanisms involved.<sup>2</sup>

*Type I* pathogenic response, known as immediate hypersensitivity, is mediated by antibodies of the IgE type that are attached to mast cells. When the antibodies are exposed to their specific antigen, the mast cells are activated and release the contents of their granules, including mediators such as histamine, several enzymes, prostaglandins, leukotrienes, and certain cytokines. In the eye, this type of response is involved in reactions such as hay fever and allergic conjunctivitis.<sup>5</sup>

*Type II* response is mediated by antibodies against cellular or matrix antigens that cause damage by one of three mechanisms: (1) activation of the complement cascade and enhanced opsonization, (2) recruitment of damaging neutrophils and macrophages, or (3) interference with functions of receptors or other molecules with specific functions. The latter mechanism is thought to be the pathogenic mechanism for Grave's disease and myasthenia gravis.<sup>35</sup>

*Type III* reaction, known also as immune complex disease, is induced by antigen-antibody complexes that initiate pathogenicity mainly by triggering the complement cascade. The systemic disease that is the hallmark for type III immunopathogenesis is serum sickness, and its experimental local model is the Arthus reaction. It is assumed that immune complexes play a major role in the pathogenesis of phacoanaphylactic endophthalmitis.<sup>28</sup>

*Type IV* immunopathogenic reaction, also named delayed hypersensitivity or cell-mediated inflammation, is induced by Th1 or Th17 lymphocytes. These cells are responsible for eradication of certain microbes and parasites, but they elicit the same processes when the targets are autoantigens. The pathogenic processes of this immune reaction have been well dissected and are detailed later. Type IV reactions were identified as the immunopathogenic mechanism in the majority of animal models for uveitic conditions, and it is assumed that they are also responsible for most cases of intraocular inflammation in humans.<sup>11,36</sup>

## IMMUNOPATHOGENIC PROCESSES OF UVEITIS IN HUMANS

It is generally assumed that processes similar to those described in experimental animals take place in humans during the development of noninfectious uveitis due to autoimmunity.<sup>11,36</sup> This notion is supported by the

finding of lymphocytes specific to ocular antigens in the blood of uveitic patients<sup>24</sup> and by the similarity in the histopathological changes<sup>4,11</sup> and in the susceptibility to immunosuppressive agents between uveitic patients and animals with EAU.<sup>11,36</sup> As mentioned earlier, small numbers of T cells with specificity toward ocular self-antigens normally escape deletion in the thymus, but the mechanism for their activation remains unclear. The finding of activation of autoreactive T cells by the gut flora<sup>32</sup> provides a new potential mechanism for the activation process, but the relatively rare occurrence of uveitis indicates that additional mechanisms are required for disease development. One such mechanism could be the adjuvant effect of systemic microbial infection mentioned earlier.<sup>33,34</sup> The finding that “licensing” in lymphoid organs is also required for autoreactive cells to initiate the pathogenic process in the target organ<sup>37,38</sup> emphasizes the complexity of the pathogenic autoimmunity.

## MECHANISMS THAT INHIBIT INFLAMMATION IN THE EYE

Ocular tissues that participate in the vision process have limited capacity for regeneration and therefore are highly susceptible to the damaging effects of inflammation. To protect against these detrimental effects, the eye is equipped with several mechanisms that together provide the eye with an immune privilege environment in which immune responses, in particular of the cellular type, are inhibited.<sup>39,40</sup> These mechanisms include:

- Poor supply of lymphatics.
- Low expression of MHC molecules.
- The presence of immunosuppressive molecules such as TGF- $\beta$ , VIP,  $\alpha$ -MSH, or Fas ligand.
- The phenomenon of anterior chamber–associated immune deviation (ACAID), in which antigenic challenge at the anterior chamber induces specific and selective suppression of Th1 and Th17-mediated cellular immunity against the eliciting antigen.<sup>39–42</sup>

# General Approach to the Uveitis Patient and Treatment Strategies

7.3

Russell W. Read

**Definition:** Uveitis is an inflammatory process that in strict definition targets the uveal tract (iris, ciliary body, choroid) primarily and other ocular structures secondarily. In common use, uveitis may refer to any form of intraocular inflammation.

**Key Feature**

- Evidence of inflammation within the eye.

**Associated Features**

- Pain, redness, photophobia, blurred vision, floaters.
- Inflammatory cells localized to intraocular structures (e.g., keratic precipitates, iris nodules, retinal vasculitis, chorioretinal infiltrates).
- Peripheral anterior synechiae, posterior synechiae, or both.
- Optic disc edema, macular edema, or both.
- Retinitis and/or retinal vasculitis.
- Secondary cataract and glaucoma.

**INTRODUCTION**

Uveitis is not a single condition but rather a category that encompasses multiple distinct conditions united by the common feature of inflammation of the uveal tract (iris, ciliary body, choroid). This inflammation may be primary or due to inflammation of adjacent structures. Uveitis is under-recognized as a cause of blindness as it is estimated to be responsible for 10%–15% of blindness<sup>1</sup> and is a leading cause of blindness in the United States.<sup>1,2</sup>

**CLASSIFICATION**

The Standardization of Uveitis Nomenclature (SUN) consensus conference workshop emphasizes an anatomical approach to uveitis classification (Table 7.3.1).<sup>3</sup> Additional descriptors are used to define the disease beyond anatomical location. These additional features include time frame of onset (sudden versus insidious); duration (limited – less than 3 months’ duration versus persistent – greater than 3 months’ duration); course (acute, recurrent, or chronic); laterality (unilateral versus bilateral); and granulomatous

versus nongranulomatous appearance. This additional information allows one to focus their differential diagnosis using a technique described under “Differential Diagnosis” later.

**EPIDEMIOLOGY**

Uveitis occurs at between 52 and 341 per 100 000 person-years in the United States.<sup>10,11</sup> Anterior uveitis is by far the most common anatomical subtype, accounting for up to 92% of cases outside uveitis referral centers,<sup>6,8</sup> with the other anatomical categories less frequently represented in community practices (see Table 7.3.1). The most common etiologies ascribed for anterior uveitis are idiopathic (38%–56%), seronegative spondyloarthropathies (21%–23%), juvenile arthritis (JA; 9%–11%), and herpetic keratouveitis (6%–10%). The majority of intermediate uveitis is idiopathic. Toxoplasmosis is the most common cause of posterior uveitis, and the most common categories of panuveitis are idiopathic (22%–45%) and sarcoidosis (14%–28%).<sup>6,9,12</sup> There is a much higher incidence of uveitis in older individuals than previously reported, with an average incidence of 340.9/100 000 persons per year in the US Medicare population of individuals age 65 years and over.<sup>10</sup>

**OCULAR MANIFESTATIONS**

The clinical manifestations of uveitis vary depending on the primary site of involvement in the eye, the course of the disease, and the presence of complications. The symptoms of acute anterior uveitis typically include pain, redness, photophobia, and blurred vision, developing over a period of hours to days. In contrast, chronic anterior uveitis (more recently termed insidious onset by the SUN nomenclature) may present with little pain or photophobia but still with blurring of vision. Intermediate and posterior uveitis typically presents with floaters or impaired vision while patients with panuveitis may present with any or all the above.

Approach to the uveitis patient must be comprehensive. The importance of a careful, complete history (including family, social, travel, and medication histories) and review of systems cannot be overemphasized. Since any intraocular or adjacent structure may yield physical examination findings that help the clinician in the development of a differential diagnosis, the ocular examination must be similarly comprehensive. The conjunctiva may show ciliary flush (perilimbal injection characteristic of anterior uveitis, Fig. 7.3.1) or nodules (e.g., in sarcoidosis), the latter of which can

TABLE 7.3.1 Classification, Clinical Features, and Epidemiology of Uveitis

**Fig. 7.3.1 HLA-B27-Related Acute Anterior Uveitis.** This severe case of anterior uveitis demonstrates fibrin clot formation and hypopyon in the anterior chamber.

**Fig. 7.3.2 Keratic Precipitates in Anterior Uveitis.** These keratic precipitates are granulomatous in appearance, as would be expected with entities such as sarcoidosis, Vogt-Koyanagi-Harada syndrome, and sympathetic ophthalmia.

be biopsied for diagnosis. The cornea may reveal keratic precipitates (collections of inflammatory cells on the endothelial surface, Fig. 7.3.2), the granulomatous or nongranulomatous character of which can further direct the differential (see Fig. 7.3.2). Keratic precipitates are normally concentrated in Arlt's triangle due to the aqueous convection currents in the anterior chamber. Keratic precipitates outside Arlt's triangle are more typical of Fuchs' heterochromic iridocyclitis or herpetic keratouveitis. Keratic precipitates are usually white when fresh and become more pigmented and shrunken ("crenated") with time. Other corneal features that may indicate herpetic disease include epithelial dendrites, geographic ulcers, or stromal scarring. Chronic uveitis may result in calcium deposition at the level of Bowman's membrane, a finding termed *band keratopathy*.

The hallmark finding in anterior uveitis is the presence of leukocytes in the aqueous humor. Breakdown of the blood-ocular barrier also results in protein leakage into aqueous, which is termed *flare*. Both are graded on a scale of 0–4+. Although a plethora of grading scales have been proposed, the SUN consensus scale has been agreed to by uveitis specialists and should be used.<sup>3</sup> With severe anterior uveitis, fibrin and hypopyon formation may be seen (see Fig. 7.3.1). Eyes with long-standing uveitis may have persistent flare that will not resolve no matter the intensity of treatment. Although this does not represent active inflammation, the presence of flare (protein) in the anterior chamber may predispose to the development of anterior or posterior synechiae. The development of 360° of posterior synechiae results in pupillary seclusion, iris bombé, and angle-closure glaucoma. Nodules in the iris (Koeppe nodules at the pupillary border; Busacca nodules within the iris stroma) or angle may be seen in granulomatous

**Fig. 7.3.3 Chronic Granulomatous Uveitis.** This patient demonstrates several features of chronic granulomatous uveitis, as may be seen with sarcoidosis, including iris nodules, posterior synechiae, and cataract formation.

uveitis (Fig. 7.3.3). Unilateral disease, elevated intraocular pressure (IOP), and sectoral iris atrophy are suggestive of herpetic disease.

Cataract is a common complication of long-standing uveitis and chronic corticosteroid therapy. Most such cataracts are posterior subcapsular in location. Posttraumatic or postsurgical cases of uveitis need to be checked carefully for capsular integrity, retained lens material, or intraocular lens (IOL) malposition.

The vitreous may show cellular infiltration, snowball opacities, fibrosis with resultant traction on the retina, or cyclitic membrane formation. It is important to determine where cells are present in the vitreous cavity. In cases of iridocyclitis, cells are found in the anterior vitreous cavity whereas with intermediate, posterior, or panuveitis, cells are distributed either throughout the vitreous or posteriorly alone.

Edema of the optic nerve, macula, or both may occur in any form of uveitis. Sheathing of retinal vessels with perivascular exudate may be seen in the periphery with intermediate uveitis or more posteriorly with posterior uveitis/retinal vasculitis. Lesions, presumably representing infiltration of inflammatory cells into the choroid, may develop, producing creamy white to yellow spots deep to the retina. More diffuse thickening of the choroid may be detectable with ultrasonography or enhanced depth imaging on optical coherence tomography (OCT). Retinal whitening indicates edema from inflammatory or infectious involvement. Hemorrhage may be present. Disruption of Bruch's membrane by inflammatory insult may lead to choroidal neovascularization. Once edema and inflammation resolve, atrophy of the retina, choroid, or both may become evident. Retinal atrophy increases the risk of retinal tears and rhegmatogenous detachment. Peripheral examination with scleral depression may reveal collections of inflammatory cells and fibrosis over the pars plana (so-called snowbanking).

In acute anterior uveitis, IOP is usually reduced due to an inflammation-induced reduction in aqueous production. With therapeutic reduction of inflammation, this is reversible. Persistent reduction in IOP may occur if chronic uveitis produces ciliary body atrophy or cyclitic membrane-induced ciliary body detachment. Potentially irreversible hypotony and eventual phthisis bulbi may occur. Elevation of IOP in uveitis results from aqueous outflow obstruction by any of a number of mechanisms, including plugging of the trabecular meshwork with inflammatory cells, swelling of meshwork fibers (trabeculitis), peripheral anterior synechiae formation, pupillary block from extensive posterior synechiae, and corticosteroid-induced IOP elevation. Gonioscopy should be performed regularly in patients with chronic uveitis to monitor for peripheral anterior synechiae formation and angle closure.

## DIAGNOSIS AND ANCILLARY TESTING

As previously mentioned, the approach to uveitis must be comprehensive (Box 7.3.1) since it may be associated with any of multiple systemic conditions, some of which may be curable (e.g., bacterial uveitis such as syphilis). Even if the disease is not curable, attention to the systemic component may be required to prevent life-threatening complications (e.g., systemic vasculitis).

**BOX 7.3.1 History Taking in Uveitis****Present Illness**

Onset, course, laterality, ocular symptoms, associated systemic symptoms

**Past Ocular History**

Previous episodes, past therapy and response, previous or antecedent ocular trauma or surgery

**Medical History**

Systemic illnesses, prodromal syndromes, medications

**Social History**

Age, race/ethnicity, gender, birthplace, travel, dietary habits, sexual history, intravenous drug abuse

**Family History**

Medical illnesses, ocular disease, history of uveitis, contagious diseases (e.g., tuberculosis), maternal infections

**Review of Systems**

General – fever, weight loss, malaise, night sweats

Musculoskeletal – arthralgias, lower back pain, joint stiffness

Dermatological – rashes, sores, alopecia, vitiligo, poliosis, tick/insect bites

Neurological – tinnitus, headache, meningism, paresthesias, weakness/paralysis, altered mental status

Respiratory – shortness of breath, cough, sputum production

Gastrointestinal – diarrhea, bloody stools, oral aphthous ulcers

Genitourinary – dysuria, discharge, genital ulcers, balanitis, epididymitis

**DIFFERENTIAL DIAGNOSIS**

Once a complete history and ocular examination with a targeted extraocular physical examination have been performed, a differential diagnosis is developed that directs a targeted diagnostic plan. One method of developing and narrowing the differential has been described as naming and meshing.<sup>13</sup> The clinical manifestations are given as specific a set of descriptors as possible using the previously mentioned classification schemes. As an example, rather than the simplistic “anterior uveitis,” a much more useful descriptor would be sudden-onset unilateral nongranulomatous anterior uveitis or insidious-onset bilateral granulomatous uveitis. Once named, this description is matched against a list of uveidities that most closely fit with those clinical characteristics (Table 7.3.2), keeping in mind other important factors such as demographics, ethnicity, and exposures. In the preceding examples, HLA-B27–associated sudden-onset anterior uveitis and sarcoidosis, respectively, most closely mesh with the descriptors. However, if the first example occurred in a Turkish national, then Behçet’s would be included in the differential as well. Once a list of potential uveitic entities has been developed, testing can be performed.

Although no definitive rules govern when a laboratory workup should be performed and what it should entail, a common practice among uveitis specialists is not to test in first episodes of unilateral nongranulomatous anterior uveitis unless specific findings on history or physical examination suggest a specific diagnosis. For any other form of uveitis, most uveitis specialists will perform a workup. A targeted approach is preferred wherein tests are ordered only for the most likely entities based on the differential generated through the naming and meshing process.<sup>9</sup> Certain entities should be tested for in virtually every uveitis patient (syphilis, tuberculosis, and sarcoid, since they may cause essentially any form of uveitis). Table 7.3.2 lists the most commonly used laboratory investigations in the workup of uveitis patients as well as the diseases for which they are useful. These tests are discussed further in the respective chapters for individual uveitic entities.

Beyond laboratory and radiographic testing, other useful ancillary tests in uveitis include angiography, both fluorescein and indocyanine green (to assess cystoid macular edema, serous retinal detachments, retinal and choroidal vascular involvement, and choroidal perfusion), ultrasonography (measurement of choroidal thickness, presence of posterior scleritis, and to rule out posterior segment pathology in eyes with media opacities), and OCT (to assess cystoid macular edema and choroidal thickening with enhanced depth imaging in addition to expanding functions like OCT angiography and en face OCT). Diagnostic vitrectomy and/or retinochoroidal biopsy can be of help in suspected cases of infectious uveitis, intraocular neoplasm, or disease nonresponsive to treatment. Specimens can be sent for histology, culture, antibody testing, electron microscopy, polymerase chain reaction (PCR) testing, and more recently, DNA deep sequencing.<sup>15</sup>

**TABLE 7.3.2 Differential Diagnosis and Laboratory Investigations for Uveitis**

Type of Uveitis	Most Common Etiologies	Laboratory Tests
Acute Anterior	Seronegative spondyloarthropathies	HLA-B27, sacroiliac films
	Behçet’s syndrome	HLA-B51
	Herpetic (HSV, VZV, CMV)	Aqueous tap for PCR
	Glaucomatocyclitic crisis	
	Poststreptococcal	Antistreptococcal lysin-O titer
	Tubulointerstitial nephritis and uveitis syndrome	HLA-DRB1*0102, <sup>14</sup> urinalysis, β2 microglobulin
Chronic Anterior	Juvenile idiopathic arthritis	Antinuclear antibodies (ANA)
	Sarcoidosis	Chest X-ray/CT, biopsy, angiotensin-converting enzyme, serum lysozyme
	Fuchs heterochromic iridocyclitis	
	Syphilis	Rapid plasma reagin (RPR), treponema pallidum antibodies
	Tuberculosis	PPD, QuantiFERON TB Gold, T-SPOT, TB, chest X-ray
Intermediate	Herpetic	Aqueous tap for PCR
	Pars planitis	
	Sarcoidosis	See above
	Lyme disease	ELISA, Western blot
Posterior	Multiple sclerosis	MRI of brain, CSF analysis
	Toxoplasmosis	ELISA
	Toxocariasis	ELISA
	Sarcoidosis	See above
	Syphilis	See above
	Tuberculosis	See above
	Viral (HSV, VZV, CMV)	Aqueous/vitreous tap/biopsy for PCR
	Birdshot choroidopathy	HLA-A29
	Serpiginous choroidopathy	
	Ocular histoplasmosis	
Panuveitis	Multifocal choroiditis/panuveitis	
	VKH disease	Fluorescein angiography, ultrasound, OCT with EDI
	Sympathetic ophthalmia	Same as for VKH, plus history
	Sarcoidosis	See above
	Toxoplasmosis	See above
	Toxocariasis	See above
	Syphilis	See above
	Tuberculosis	See above
	Endophthalmitis	Vitreous culture

See subsequent chapters for detailed description of each entity. CMV, Cytomegalovirus; CSF, cerebrospinal fluid; CT, computed tomography; EDI, enhanced depth imaging; ELISA, enzyme-linked immunosorbent assay; HLA, human leukocyte antigen; HSV, herpes simplex virus; MRI, magnetic resonance imaging; OCT, optical coherence tomography; PCR, polymerase chain reaction; PPD, purified protein derivative; TB, tuberculosis; VKH, Vogt-Koyanagi-Harada; VZV, varicella-zoster virus.

**TREATMENT**

The goal of the treatment of eye disease is to protect and preserve visual function. In uveitis, treatment must be directed toward potentially two separated but intimately related processes: elimination of infection (if present) and suppression of the host inflammatory response. Up to 90% of uveitis is noninfectious, so the latter is most commonly the sole target, but the former must never be removed from consideration when planning treatment. Once the decision is made to treat, any and all means of immunosuppression must be considered in the pursuit of that goal. Therapy may be administered via any of multiple routes (topical, periocular, intraocular, systemic) using any of the multiple therapeutic categories of anti-inflammatories now available. If the ophthalmologist is not comfortable or familiar with therapy beyond that applied to the eye or systemic corticosteroids, then they must refer or collaborate with someone who is. The most common anti-inflammatory medications used in the treatment of uveitis are outlined in Table 7.3.3. Therapies for specific types of uveitis are detailed in subsequent chapters.

TABLE 7.3.3 Anti-inflammatory Therapy in the Treatment of Uveitis

Drug Class	Medication	Mechanism of Action	Side Effects	Comments
Glucocorticoids	Prednisone, methylprednisolone sodium succinate, triamcinolone acetonide, dexamethasone, fluocinolone acetonide, difluprednate, prednisolone acetate, prednisolone sodium phosphate, loteprednol etabonate, rimexolone	Engagement of cytosolic corticosteroid receptor with transportation into nucleus and subsequent myriad effects, including inhibition of cyclo-oxygenase and lipoxygenase pathways, decreased production of vasoactive amines and interleukins, decreased circulating monocytes, decreased macrophage activity, decrease in complement levels. Pleiotropic effects are the basis of the significant side effects	<b>Topical</b> – elevated IOP, cataract, increased susceptibility to infection, corneal or scleral thinning/perforation <b>Periocular</b> – same as topical, as well as ptosis, scarring of Tenon's capsule, scleral perforation, hemorrhage, abscess <b>Systemic</b> – same as topical, as well as weight gain, fluid retention, electrolyte disturbances, osteoporosis, aseptic necrosis of hip, hypertension, impaired glucose tolerance, mental status changes, impaired wound healing, menstrual irregularities, others	Most versatile agent but also one with most potential side effects, especially with chronic use May be used topically, intraocularly, periocularly, orally, intravenously
Antimetabolites	Methotrexate	Increase in extracellular adenosine, increase in intracellular cAMP result in immunosuppression <sup>36</sup>	Hepatotoxicity, GI upset, pneumonitis, stomatitis, bone marrow suppression, teratogenicity, increased risk of infection	Given weekly, orally or subcutaneously
	Mycophenolate mofetil	Inhibits lymphocyte purine synthesis by inhibition of inosine monophosphate dehydrogenase	Diarrhea, nausea, bone marrow suppression, teratogenicity, increased risk of infection	Daily oral use
	Azathioprine	Alters purine metabolism	GI upset, hepatitis, bone marrow suppression, teratogenicity, increased risk of infection	Daily oral use
T-cell inhibitors	Cyclosporine	Inhibits T cells via inhibition of calcineurin by binding to cyclophilin	Renal toxicity, hypertension, hirsutism, tremor, teratogenicity, increased risk of infection	Daily oral use
	Tacrolimus	Inhibits T cells via inhibition of calcineurin by binding to FK binding protein	Renal toxicity, hypertension, neurotoxicity, hepatitis, diabetes	Daily oral use
	Abatacept	Decoy receptor that blocks activation of T cells by preventing binding to costimulatory molecules on antigen-presenting cells	Increased risk of infection, headache, upper respiratory tract infection, sore throat, and nausea	Has shown efficacy in JA-associated uveitis Intravenous infusion every 4 weeks after initial loading schedule or subcutaneous weekly
B-cell inhibitors	Rituximab	Monoclonal antibody that binds to CD20 resulting in depletion of circulating and tissue-based B cells	Increased risk of infection, severe skin and mouth reactions, PML, nausea, diarrhea, headache, muscle spasms, anemia, peripheral edema	Varies; for RA, two infusions given two weeks apart every 24 weeks
Alkylating agents	Cyclophosphamide	Lymphotoxicity, crosslinks DNA	Hemorrhagic cystitis, sterility, increased risk of malignancy, bone marrow suppression, teratogenicity, increased risk of infection	Daily oral or monthly intravenous infusion
	Chlorambucil	Lymphotoxicity, crosslinks DNA	Sterility, increased risk of malignancy, bone marrow suppression, teratogenicity, increased risk of infection	Daily oral or short-term high-dose regimen <sup>16</sup> Alkylating therapy has the greatest potential to induce a long-term drug-free remission
Cytokine inhibitors	Adalimumab, certolizumab pegol, golimumab, infliximab, and etanercept	Inhibits TNF- $\alpha$ via an anti-TNF- $\alpha$ antibody (all but etanercept) or via a decoy receptor (etanercept)	GI upset, headache, development of antinuclear antibodies (ANA), possible lupus-like syndrome, increased risk of infection (especially TB), exacerbation of multiple sclerosis, worsening of heart failure	Varies depending on agent Intravenous infusion, subcutaneous injection (weekly to monthly depending on agent) <sup>17</sup>
	Anakinra	IL-1 receptor antagonist	Increased risk of infection, headache, nausea, diarrhea, sinusitis, arthralgia, flu-like symptoms, abdominal pain	Daily subcutaneous injection
	Tocilizumab	Monoclonal antibody against IL-6	Increased risk of infection, GI perforation, headache, hypertension, increased ALT	Efficacy for uveitis reported <sup>18</sup> Intravenous infusion every 2–4 weeks
Lymphocyte migration inhibitors	Natalizumab	Monoclonal antibody against $\alpha$ 4-integrin, an adhesion molecule involved in lymphocyte migration into bowel and central nervous system	Increased risk of infection, including PML	Monthly intravenous infusion
	Fingolimod	Sphingosine-1-phosphate receptor modulator; inhibits release of lymphocytes from lymph nodes into circulation	Decreased heart rate, increased risk of infection, macular edema	Daily oral use
Interferon	Interferon- $\alpha$ , $\beta$ interferon	Both bind to same interferon receptor and mediate multiple biological effects	Myalgias, fever, depression	Successful reports in Behçet's, <sup>19</sup> macular edema <sup>20,21</sup> Subcutaneous, schedule varies but up to once daily
Complement inhibitors	Eculizumab	Monoclonal antibody against complement component C5	Increased risk of infection, headache, nasopharyngitis, back pain, nausea, hypertension	No human data in uveitis, animal studies show efficacy in experimental uveitis <sup>22</sup> Use is restricted to registered healthcare professionals Intravenous infusion

\*While commercially available in the United States, many of these agents have little or no human uveitis data available. None should be used by individuals without experience in their use and monitoring.

ALT, Alanine aminotransferase; cAMP, cyclic adenosine monophosphate; GI, gastrointestinal; IOP, intraocular pressure; JA, juvenile arthritis; PML, progressive multifocal leukoencephalopathy; RA, rheumatoid arthritis; TB, tuberculosis; TNF- $\alpha$ , tumor necrosis factor alpha.

## Mydriatic and Cycloplegic Agents

Anterior uveitis results in irritation of the ciliary muscle, causing spasms that produce the stereotypical photophobia. Cycloplegics act by preventing ciliary muscle contraction, reducing pain. The release of fibrin and other serum components into the anterior chamber during anterior uveitis may result in adhesions forming between the iris and anterior lens capsule (posterior synechiae) and the peripheral iris and angle (peripheral anterior synechiae). Depending on the duration of action and frequency of instillation, mydriatics result in movement of the iris, reducing the opportunity for synechiae formation. In addition, cycloplegia shifts the lens–iris diaphragm posteriorly, deepening the angle and reducing the opportunity for peripheral anterior synechiae to form. Sometimes posterior synechiae still form even with the use of mydriatic/cycloplegic agents, but at least use of these agents should result in a dilated pupil that still allows fundus examination. Multiple agents are available, including (in order of increasing duration) tropicamide, cyclopentolate, homatropine (no longer widely available), scopolamine, and atropine. Each has advantages and disadvantages. Shorter-acting agents tend to keep the pupil moving more than longer-acting agents, though they require patient compliance with multiple drops per day. Longer-acting agents may be used less frequently, reducing the dependency on compliance, but may result in synechiae formation in a dilated state, which may be unappealing to patients.

## Nonsteroidal Anti-inflammatory Drugs

As a primary treatment modality for ocular inflammatory diseases, nonsteroidal anti-inflammatory drugs (NSAIDs) are generally ineffective, other than oral agents in some cases of non-necrotizing scleritis. NSAIDs may provide some utility as an adjunct to other forms of therapy (especially topically in cystoid macular edema) or for prophylaxis against recurrent disease. Oral NSAIDs and oral corticosteroids should not be used concurrently because of the increased risk of gastric ulceration.

## Corticosteroids

Corticosteroids remain the most effective, most rapidly acting anti-inflammatory agents and thus are the first line of therapy in most cases of noninfectious uveitis. Corticosteroids produce broad suppression of the immune system by a number of mechanisms (see [Table 73.3](#)) but also may produce significant side effects. Corticosteroids may be given locally (topical, periocular, intraocular) or systemically (oral or intravenous).

### Topical

Topically applied corticosteroids penetrate the posterior segment of phakic eyes poorly, thus topical administration is useful primarily in patients with anterior uveitis and for the anterior component of panuveitis. A basic paradigm for the use of any corticosteroid, including topical formulations, is “use enough, soon enough.” In other words, early, aggressive use is required. To accomplish this, barring other considerations such as cost and availability, the most potent agent that can be safely used should be. Multiple agents exist in topical ophthalmic formulation, including (in order of decreasing clinical potency) difluprednate, prednisolone acetate, prednisolone sodium phosphate, rimexolone, loteprednol etabonate, and fluorometholone. Each has unique pharmacological and pharmacokinetic properties that may provide advantages and disadvantages in certain clinical scenarios. Patients with a history of corticosteroid-response IOP elevation should be monitored carefully and appropriate measures taken to control IOP while on corticosteroids.

### Periocular

The periocular route is a reasonable choice for unilateral disease or bilateral disease in a patient who has contraindications to—or refuses to take—systemic corticosteroids, and it may be particularly effective for cystoid macular edema. Injection is performed via a superior sub-Tenon’s capsule or inferior transseptal approach and requires only topical anesthesia. Longer-acting agents (e.g., triamcinolone acetonide) are preferred and may be given every 3–4 weeks until the desired effect is achieved or a plateau in effect is reached. Periocular injections of corticosteroids should not be used acutely in cases of infectious uveitis (e.g., acute retinal necrosis syndrome, toxoplasmosis) and should be used with caution in patients who have a history of corticosteroid-induced IOP elevation due to the extended duration of effect of depot formulations such as triamcinolone acetonide.

### Intravitreal

Corticosteroids can be delivered intravitreally by injection of a suspension (triamcinolone acetonide), degradable implant (dexamethasone intravitreal implant), or by surgical implantation of a sutured sustained-release device (fluocinolone acetonide). Duration of effect varies with intravitreal injections having a shorter duration (up to several months) as compared to the sustained-release implant (2.5 years). As with any form of corticosteroid, cataract formation and elevation in IOP are potential adverse effects but can usually be managed by standard means. Finally, though rare, endophthalmitis may occur due to the invasive nature of the procedure.

### Systemic

Systemic corticosteroids (oral or intravenous) have the broadest utility and are useful in all forms of uveitis. Initiating therapy at a high dose followed by tapering once an effect is achieved is more effective and reduces the overall burden of exposure compared to beginning at a lower dose with subsequent increases because of poor response. A pulse of oral corticosteroids can be given with no taper if the duration is less than two weeks, but therapy beyond this period necessitates a tapering schedule due to adrenal suppression. Patients on long-term corticosteroid therapy should receive calcium and vitamin D supplementation, as well osteoporosis monitoring and prophylaxis. Oral therapy is most commonly accomplished using prednisone (1 mg/kg/day, maximum of 60 mg/day of prednisone) while intravenous therapy may consist of methylprednisolone 1 gram per day for 3 days, followed by an oral prednisone taper. Too rapid a taper may result in rebound disease and a mistaken assumption that oral prednisone is not effective. Conversely, too slow a taper results in prolonged exposure to higher than needed doses and increases the incidence of side effects. In no case should a patient be maintained on chronic oral prednisone at a dose greater than 7.5 mg per day. If a dose greater than this is required for disease control or if disease is not controlled at the maximum dose within 4 weeks, then institution of immunosuppressive therapy is necessary.

## Immunosuppressive Therapy

Immunosuppressive therapy plays a vital role in the treatment of noninfectious uveitis, allowing one to achieve control of disease in patients who have not responded adequately to—or who develop side effects from—corticosteroid therapy.<sup>23</sup> These agents are safe and effective, and counseling of any other nature is a disservice to patients. However, only individuals comfortable in monitoring the side effects of these medications should assume primary control over therapy. If the individual ophthalmologist is not comfortable in that role, then referral to a uveitis specialist should occur. If a uveitis specialist is not available, then partnership with a rheumatologist or hematologist/oncologist can be fruitful. Prompt, accurate communication between ophthalmologist and the prescribing specialist ensures that such therapy is successful by monitoring for complete control of uveitis, reduction of the risk of ocular complications, and avoidance of adverse events.

A variety of immunosuppressive medications exist, and [Table 73.3](#) summarizes the most commonly used agents, their mode of action, and their potential side effects. Little comparative effectiveness data exists to guide the selection of a specific agent for a specific condition. Rather, most specialists chose an agent based on familiarity, side-effect profile, and comorbidities of the patient. Antimetabolites are a frequent first choice. If these agents are incompletely successful, then an additional agent is added to the regimen, currently a biological agent—TNF inhibitor being the most common, though additional antimetabolites or a T-cell inhibitor are viable alternatives. If the initial agent chosen provides minimal or no benefit, then a trial of a separate antimetabolite may be warranted. If a combination of agents (e.g., antimetabolites, T-cell inhibitors, biologics) is unsuccessful, then advancing to alkylating agents may be warranted. While they carry the potential for significant toxicity, alkylating agents are the medications most likely to induce a long-term drug-free remission.

## COURSE AND OUTCOME

Uveitis may cause visual loss and blindness due to a variety of causes, including secondary complications such as cataract, glaucoma, choroidal neovascularization, cystoid macular edema, optic neuropathy, and others. Cataract extraction can be safely accomplished in uveitic eyes, but should ideally be performed only after quiescence has been achieved, by whatever means necessary, for 3–4 months. This does not mean that the patient has to be off therapy and under control for that period, rather that they are under control using whatever medication regimen is required.

Small-incision ultrasonic phacoemulsification is the preferred technique due to less manipulation of the eye. Eyes with significant vitritis often benefit from combined cataract extraction and pars plana vitrectomy.<sup>24</sup> With the exception of patients with chronic juvenile arthritis–associated uveitis, if quiescence is achieved and maintained, most eyes tolerate a posterior chamber intraocular lens (PCIOL).<sup>25</sup> Eyes with a proclivity to form posterior synechiae or patients in whom compliance has been an issue should be considered for aphakia. Patients with inflammation centered around the pars plana region tend to have a higher complication rate than those with other types of uveitis.<sup>26</sup>

Ocular hypertension and glaucoma may occur in uveitic eyes via a variety of mechanisms, as previously discussed. Medical therapy is the reasonable first line agent for IOP control. Any of the modern agents are acceptable, though prostaglandin analogs may worsen cystoid macular edema.<sup>27</sup> Previous concerns about exacerbating uveitis with these agents is probably not warranted for certain agents.<sup>28</sup> In cases of pupillary block, iridectomy should be performed. Laser iridectomy is easier to perform than surgical iridectomy and if made large enough and with argon laser pretreatment, may remain patent. However, with closure, surgical iridectomy should be performed. If filtering surgery is necessary, the use of antimetabolites (e.g., mitomycin) or aqueous drainage devices greatly increases the success rate in these patients.<sup>29,30</sup>

Uveitis is frequently complicated by cystoid macular edema (CME), which can result in irreversible visual loss. The first goal in treatment of CME is control of the underlying inflammatory disease. If the uveitis is controlled, then periocular, intravitreal, or systemic corticosteroids may be successful. Therapeutic vitrectomy may also be beneficial in some cases. Various other agents have been tried for uveitic CME with varying success, including acetazolamide,<sup>31</sup> octreotide,<sup>32</sup> interferon,<sup>20</sup> and tocilizumab.<sup>33</sup>

Retinal detachment may occur in uveitis as a serous detachment (e.g., with Vogt–Koyanagi–Harada [VKH] syndrome, which should respond to anti-inflammatories), as a rhegmatogenous detachment (e.g., from the retinal atrophy induced by acute retinal necrosis syndrome), or as a

tractional detachment from fibrosis due to any number of uveitic conditions, both of which require surgical intervention.

Chronic uveitis may lead to hypotony through aqueous hyposecretion as a result of damage to the aqueous-producing nonpigmented ciliary epithelium or by cyclitic membrane formation with ciliary body detachment. The reduction in aqueous production leads to decreased nutrient supply to anterior segment structures and further complications such as corneal edema. Cyclitic membranes may be removed surgically, which may allow reattachment of the ciliary body and return of normal aqueous production, depending on the time frame of detachment. Attempts to increase aqueous production pharmacologically, while initially promising, have over the long term been generally disappointing.<sup>34</sup> Some benefit may be gained by injection of intravitreal viscoelastics.<sup>35</sup> Chronic hypotony may result in phthisis bulbi. This and other dire consequences of uveitis are the result of inadequate control of inflammation. Thus elimination of inflammation as early as possible in the course of uveitis is vital to preserve visual function.

# 7.4

## HERPES SIMPLEX AND VARICELLA ZOSTER

### HERPETIC ANTERIOR UVEITIS

**Definition:** Chronic recurrent unilateral anterior uveitis caused by herpes simplex virus (HSV) or varicella zoster virus (VZV).

#### Key Features

- Ocular hypertension.
- Iris atrophy.
- Minimal or no vasculitis and vitritis.

#### Associated Features

- Keratitis.
- Pigmented keratic precipitates.

### VARICELLA-ZOSTER AND HERPES SIMPLEX VIRUS-INDUCED ACUTE RETINAL NECROSIS

**Definition:** A necrotizing retinitis caused by infection with VZV or HSV (rarely cytomegalovirus) in an immunocompetent host.

#### Key Features

- Severe uveitis or vitritis.
- Retinal vasculitis.
- Retinal necrosis.

#### Associated Features

- Keratic precipitates.
- Optic neuritis.
- Retinal detachment.

### PROGRESSIVE OUTER RETINAL NECROSIS

**Definition:** A necrotizing retinitis caused by infection with VZV or HSV in an immunocompromised host.

#### Key Features

- Multifocal lesions.
- Retinal necrosis.
- Minimal or no vasculitis and vitritis.

#### Associated Features

- Rapid progression.
- Poor prognosis.

## HERPES SIMPLEX VIRUS AND VARICELLA-ZOSTER VIRUS

### INTRODUCTION

HSV (represented by HSV-1 and HSV-2 serotypes) and VZV are members of *Herpesviridae*, a family of double-stranded DNA viruses

### EPIDEMIOLOGY AND PATHOGENESIS

HSV types 1 and 2 are ubiquitous, infecting the majority of world's population. HSV is the leading cause of herpetic anterior uveitis. It is the second leading cause (following VZV) of acute retinal necrosis (ARN), being more frequent in younger adults and children, however.<sup>1</sup> Following primary infection, the virus enters a dormant stage in the trigeminal ganglion. Episodes of reactivation lead damage of downstream tissues innervated by the trigeminal nerve.

Varicella (chickenpox) is a syndrome that occurs in the course of the primary infection with VZV. Following the primary infection, the virus establishes life-long latency in the sensory ganglia. Prior to the introduction of the varicella vaccine in 1995, infection with VZV was nearly universal in the United States. Herpes zoster (HZ) or shingles is a secondarily reactivated infection.<sup>2</sup> Herpes zoster ophthalmicus (HZO) is an outbreak of HZ occurring along the ophthalmic branch of the trigeminal nerve. VZV uveitis may be associated with HZO, but frequently it is seen in isolation. Progressive outer retinal necrosis (PORN) is a severe rapidly progressive retinitis caused by VZV.

### OCULAR PRESENTATION

Although considerable effort was spent attempting to delineate differentiating clinical features of HSV and VZV uveitis, there are no clear boundaries distinguishing HSV and VZV-associated syndromes.<sup>1,3</sup> Here we discuss HSV and VZV-associated disease in the context of their shared syndromes.

Herpetic anterior uveitis is typically a unilateral condition. It can demonstrate robust anterior chamber cell and flare. Frequently there is evidence of concurrent or previously healed keratitis. Eye pressure can be elevated, sometimes severely, even with a gonioscopically open anterior chamber angle. Pigmented keratic precipitates (KP) are common. In some cases the iris is severely affected, displaying sectoral atrophy.<sup>4,5</sup>

ARN syndrome presents with panuveitis with the vitreous frequently showing marked inflammatory cell and haze. The retina shows discrete areas of whitening, typically located in the far to midperiphery, that represent retinal necrosis, the hallmark of this infection. The retinitis spreads rapidly in a circumferential fashion in the absence of treatment. Associated occlusive retinal vasculitis involving the arteries leads to areas of nonperfusion and ischemia.<sup>6</sup> Involvement of the optic nerve is common (Fig. 7.4.1, Table 7.4.1). Rhegmatogenous retinal detachment originating in the areas of retinal necrosis is very common, occurring in up to 75% of affected eyes.<sup>1,7</sup> Epiretinal membranes and proliferative vitreoretinopathy are other complications. Viral meningoencephalitis may develop. There is a high risk of the fellow eye involvement, especially in the first three months. It is important to recognize that HSV/VZV retinitis encompasses a spectrum of disease severity. The ARN is the canonical presentation, but non-necrotizing disease has been described.<sup>8,9</sup>

PORN is an aggressive form of herpetic retinitis. The majority of cases are secondary to VZV in patients with advanced acquired immune deficiency syndrome (AIDS) with CD4-positive T lymphocyte count less than 50. PORN is characterized by multifocal deep retinal lesions that can be in all three retinal zones. These lesions rapidly progress to full-thickness

retinal necrosis and become confluent, leading to profound vision loss. Retina in immediate proximity to vessels clinically appears free of retinitis, producing a so-called cracked mud. Involvement of the optic nerve, including retrobulbar optic nerve damage, is common. Characteristically, there is relative paucity of inflammatory response. Unlike in ARN, retinal vasculitis is seen infrequently and tends to be mild. Retinal detachment is common<sup>10,11</sup> (see Table 7.4.1).

Characteristic features can aid in clinical diagnosis of herpetic uveitis, but laboratory diagnosis should be sought in ambiguous cases. Presently polymerase chain reaction (PCR) techniques have supplanted other modalities as they demonstrate a marked superiority in terms of sensitivity and specificity.<sup>12</sup> In cases of ARN, aqueous samples provide detection rates similar to vitreous samples.<sup>13,14</sup> Quantitative PCR offers additional diagnostic utility by reliably detecting even a low viral load and enabling the monitoring treatment response over time. Goldmann–Witmer coefficient (GWC) is a measure of local ocular antibody production in response to the pathogen. This test may be more beneficial later in the course of the disease, once sufficient antibody response to the pathogen has mounted.

## DIFFERENTIAL DIAGNOSIS

In the case of isolated anterior uveitis, the differential diagnosis includes HLA-B 27 related anterior uveitis, sarcoidosis, tuberculosis, syphilis, Posner–Schlossman syndrome, and Fuchs’ heterochromic iridocyclitis. The differential diagnoses of ARN and PORN are similar, including syphilitic retinitis, ocular toxoplasmosis, cytomegalovirus (CMV) retinitis, Behçet’s disease, ocular lymphoma, sarcoidosis, collagen vascular diseases, and endophthalmitis.

## PATHOLOGY

Histopathology of ARN demonstrates inflammatory infiltrates involving all ocular tissues. Occlusive retinal vasculitis is observed. Marked

Fig. 7.4.1 Acute Retinal Necrosis—Subacute Stage.

necrosis is present in the retina as well as the optic nerve. Intranuclear inclusion bodies are present in the retina and retinal pigment epithelium (RPE). Electron microscopy demonstrates herpes viral particles.<sup>15,16</sup>

PORN demonstrates areas of severe retinal necrosis with mild to moderate inflammatory cell infiltration. The optic nerve is affected by necrosis and inflammation. Intranuclear inclusion bodies can be seen but are variable, and electron microscopy may demonstrate herpes virus particles within retina cells.<sup>10,17</sup>

## TREATMENT

Herpetic anterior uveitis is typically managed with systemic antivirals, oral acyclovir (800 mg five times daily) or valacyclovir (1 g three times daily), in combination with topical corticosteroids. The latter should not be used with antiviral coverage during the acute phase. Chronic maintenance therapy with a low-dose corticosteroid is often required.

Historically, the therapy of choice for ARN was intravenous acyclovir (10 mg/kg 3 times a day induction therapy for a week) followed by oral acyclovir (800 mg 5 times a day for at least 6 weeks) as maintenance. Oral acyclovir is insufficient for induction, but it is frequently employed for prophylaxis for one to three months and indefinitely in some patients. Valacyclovir (used as 1–2 g orally, three times daily), famciclovir (500 mg orally, three times daily), and valganciclovir (900 mg orally, twice daily) are newer oral outpatient alternatives to intravenous acyclovir. Systemic corticosteroids may be used to minimize the intraocular inflammation. Oral antiplatelet agent aspirin is occasionally employed to limit retinal vascular complications. Intravitreal injection of foscarnet (2.4 mg/0.1 mL) or ganciclovir (2 mg/0.1 mL) can be used in addition to systemic therapy.<sup>18</sup> Utility of prophylactic vitrectomy with or without intraoperative acyclovir lavage in preventing retinal detachment was demonstrated but is not universally accepted.<sup>7</sup> Similarly, prophylactic laser barricade of the uninvolved retina is used by some practitioners.<sup>14,18</sup>

PORN is frequently refractory to therapy. Single antiviral agent systemic therapy almost always fails. Combinations of acyclovir and/or foscarnet and/or ganciclovir given intravenously have been reported as effective in halting disease progression.<sup>19</sup> Augmentation with intravitreal injection of antivirals appears to offer further advantage.<sup>20</sup> Use of prophylactic laser barricade applied proximally to the affected areas of the retina may lessen incidence of retinal detachment. Retinal detachment usually requires vitrectomy and use of silicone oil or in some cases gas tamponade.

## COURSE AND OUTCOME

Overall, herpetic anterior uveitis carries a favorable prognosis. Secondary glaucoma, cataract, keratitis, and cystoid macular edema are common complications. The disease tends to have a relapsing course.

Because of its aggressive, rapidly progressive course and frequent occurrence of optic nerve involvement and retinal detachment, ARN carries a guarded visual prognosis. Retinal detachment occurs in 70% of untreated cases and in 50% with antiviral treatment. Less than half of patients retain ambulatory vision in their affected eyes.

Original reports of PORN supported a universally poor prognosis with loss of vision to no light perception. The modern approach with use of systemic and intravitreal newer generation antivirals and HIV therapy appears to have improved the prognosis, with up to half of patients retaining ambulatory vision. Retinal detachment develops in 70% of affected eyes. Survival of patients is influenced by the status of the underlying systemic disease, most commonly AIDS.

TABLE 7.4.1 Posterior Segment Findings in ARN, PORN, CMVR, and EBV Choroiditis

	Vascular Changes	Retinal Changes	Vitreous	Retinal Pigment Epithelium Changes	Optic Nerve Changes
ARN	Occlusive vasculitis, prominent sheathing	Confluent areas of whitening/necrosis, hemorrhages	Marked vitritis	Pigmentary clumping and mottling (late finding)	Optic neuropathy, optic atrophy (late)
PORN	Paucity of vasculitis, perivascular sparing of the retina	Multifocal retinal whitening/necrosis that appears to involve outer retina	Mild inflammation	Pigmentary clumping and mottling (late finding)	Optic neuropathy, optic atrophy (late)
CMVR	Occlusive retinal vasculitis, prominent sheathing, “frosted branch” angiitis	Macular edema, areas of white retinal necrosis or granular retinitis, abundant intraretinal hemorrhages	Variable, usually mild, inflammation	Granular RPE atrophy	Optic neuritis
EBV			Vitritis present	Multifocal choroiditis, punched-out areas	

ARN, Acute retinal necrosis; CMVR, cytomegalovirus retinitis; EBV, Epstein–Barr virus; PORN, progressive outer retinal necrosis; RPE, retinal pigment epithelium.

## CYTOMEGALOVIRUS

### CYTOMEGALOVIRUS RETINITIS

**Definition:** A necrotizing retinitis caused by infection with cytomegalovirus (CMV) in an immunocompromised host.

#### Key Features

- Retinal vasculitis.
- Retinal necrosis.
- Progression to bilateral disease if untreated.

#### Associated Features

- Optic neuropathy.
- Mild vitritis.
- Atrophic healed retina.

### CYTOMEGALOVIRUS-ASSOCIATED ANTERIOR UVEITIS

**Definition:** A chronic recurrent unilateral anterior uveitis caused by CMV.

#### Key Features

- Ocular hypertension.
- Nodular keratic precipitates.
- Low-grade anterior chamber inflammation.

#### Associated Features

- Corneal endotheliitis.
- Iris atrophy.
- Paucity of posterior synechiae.

## INTRODUCTION

CMV is a member of the *Herpesviridae* family. Primary infection is very common in the general population and is frequently asymptomatic. However, CMV causes severe infections in immunocompromised patients.

## EPIDEMIOLOGY AND PATHOGENESIS

Primary CMV infection typically occurs following mucous membrane contact with contaminated bodily fluids. Latency is established following the original infection. The infection affects both genders equally and is very common in both children and adults, ultimately with the majority of adult population demonstrating evidence of exposure. CMV can reactivate in the setting of immunosuppressed states (particularly T-cell dysfunction) leading to involvement of a variety of organ systems. CMV retinitis (CMVR) is tightly linked to the AIDS epidemic, with the majority of patients having CD4+ lymphocyte counts of less than 50.

CMV has also been established as an etiological agent of anterior uveitis. It appears to be the cause of at least some cases of Posner–Schlossman glaucomatocyclitic crisis syndrome and occasionally can produce ocular findings of Fuchs' heterochromic iridocyclitis.<sup>21</sup> CMV-associated anterior uveitis typically affects healthy adults.

## OCULAR MANIFESTATIONS

Symptoms of CMVR include photopsia, loss of vision, and floaters. Eye pain is uncommon, and disease can be asymptomatic. CMVR typically starts as a solitary white retinitis lesion with a granular border (Figs. 7.4.2 and 7.4.3). Vasculitis is usually prominent resulting in ischemia and hemorrhages (see Table 7.4.1). If there is direct involvement of the optic nerve, a concurrent central nervous system infection is common. Associated inflammation is usually mild.<sup>22</sup> Stellate KP may be observed. When first presenting in one eye, CMVR subsequently involves the other.<sup>23</sup>

CMV-associated anterior uveitis has a chronic recurrent course characterized by episodes of elevated eye pressure concurrent with active

**Fig. 7.4.2** Cytomegalovirus Retinitis Involving the Posterior Pole, Threatening the Fovea.

**Fig. 7.4.3** Cytomegalovirus Affecting the Optic Nerve Head and the Peripapillary Retina.

inflammation marked by mild anterior chamber cell and flare. Corneal edema is frequently observed.<sup>24</sup> Nummular areas of corneal endotheliitis associated with characteristic nodular medium KP may be present.<sup>25</sup> Iris atrophy is frequently present. Between episodic recurrences, the anterior chamber may appear quiet, and intraocular pressure (IOP) tends to normalize.

## DIAGNOSIS

CMVR can be diagnosed on clinical grounds, especially in patients at high risk for the disease, such as those with AIDS. PCR of ocular fluid offers the highest utility when laboratory confirmation is necessary. Both aqueous and vitreous samples are adequate substrates for PCR.<sup>26,27</sup>

Diagnosis of CMV-associated anterior uveitis is made clinically and can be confirmed by PCR of aqueous fluid, but its sensitivity is limited. Quantitative PCR techniques have an advantage of circumventing false-positive results stemming from detection of CMV latently infecting leukocytes.

## DIFFERENTIAL DIAGNOSIS

CMVR can be mimicked by ARN, toxoplasma retinitis, syphilitic retinitis, tuberculosis, Behçet's disease, and, rarely, ocular lymphoma or leukemia, endogenous bacterial or fungal endophthalmitis, and sarcoidosis. HSV and VZV anterior uveitis, HLA-B27-associated disease, and Fuchs' heterochromic iridocyclitis can be considered in the differential diagnosis of CMV-associated anterior uveitis.

## **PATHOLOGY**

Histologically, CMVR is characterized by extensive coagulative necrosis with display of cytomegalic cells in all layers of the retina and RPE. Inclusion bodies can be observed within both the nuclei and cytoplasm of affected cells. Herpetic viral particles can be demonstrated by electron microscopy.<sup>28,29</sup>

In vivo confocal microscopy studies of endotheliitis lesions associated with CMV anterior uveitis demonstrate enlarged endothelial cells with a highly reflective intranuclear material surrounded by a hyporeflective halo. These “owl’s eye” cells are thought to represent CMV cytomegalic cells.<sup>30</sup>

## **TREATMENT**

CMVR is treated with systemic or intravitreal administration of antiviral agents. Systemic therapy can control the disease at extraocular sites and prevent involvement of the fellow eye but has adverse effects of medication. Oral ganciclovir tends to be less effective. Valganciclovir offers improved bioavailability and can be used both for induction and maintenance therapy. It is typically started at 900 mg bid. Bone marrow suppression with neutropenia is a serious side effect.<sup>31</sup> Intravitreal ganciclovir injections of 2 mg weekly are a therapeutic alternative.<sup>32</sup> Vitrasert, a no-longer-manufactured, surgically implanted ganciclovir slow-release intraocular device offered local antiviral action for up to eight months. Foscarnet and cidofovir are other therapeutic options. Renal toxicity is a common and serious side effect of both agents. When injected intravitreally, foscarnet is administered as 2.4 mg once or twice a week.<sup>33</sup> Intravitreal cidofovir is administered as a 20-µg dose given every 5 weeks. Both local and systemic use of cidofovir is associated with ocular toxicity, including iritis and hypotony.

Therapy with systemic and topical ganciclovir, oral valganciclovir, intravitreal ganciclovir, and ganciclovir implant for CMV anterior uveitis has been reported. These medications may be helpful in treatment of acute episodes of uveitis and may extend the time interval between relapses.<sup>34,35</sup> Glaucoma medications and topical corticosteroids are employed to control intraocular pressure and inflammation.

## **COURSE AND OUTCOME**

Medications to treat CMV are virustatic and not virucidal, therefore treatment of CMVR must be indefinite in an immunodeficient patient. Moreover, drug resistance develops during the course of maintenance therapy, leading to clinical disease reactivation that requires reinduction with escalating doses of medication or switching to a new antiviral agent. Development of CMVR is an independent risk factor for death in patients with AIDS. Use of highly active antiretroviral therapy (HAART) has dramatically altered the course of the disease. The incidence of retinal detachment has been significantly reduced, and the retinitis itself appears to have a milder course in patients receiving HAART.<sup>36,37</sup> Reconstitution of immune repertoire allows eventual discontinuation of maintenance therapy for CMV in many patients. Chronic anterior and intermediate uveitis, termed immune recovery uveitis (IRU), may develop as a response to viral antigens.<sup>38</sup>

CMV anterior uveitis tends to have a chronic course with episodic flares. The quiescent interval is variable, from weeks to many months. Cataract formation and persistence of IOP elevation outside the flare episodes are frequently encountered and may require surgery. In cases associated with corneal endotheliitis, corneal edema and cell loss may affect visual function. Overall visual prognosis is favorable.<sup>34,39</sup>

## **EPSTEIN–BARR VIRUS**

### **INTRODUCTION**

Epstein–Barr virus (EBV) is a double-stranded DNA virus of the *Herpesviridae* family. It is believed to be an uncommon cause of uveitis.

## **EPIDEMIOLOGY AND PATHOGENESIS**

It is transmitted through exchange of saliva or blood transfusions. By adulthood, most people have acquired an infection with the virus. EBV is the causative agent of infectious mononucleosis, and it is also associated with Burkitt’s lymphoma and other B-cell malignancies seen in immunosuppressed patients.

## **OCULAR MANIFESTATIONS**

EBV uveitis can manifest as iritis, whereas posterior segment involvement may include multifocal choroiditis characterized by punched-out areas of pigment epithelial changes and vitritis (see [Table 74.1](#)).<sup>40</sup>

## **DIAGNOSIS AND ANCILLARY TESTING**

Immunoglobulin M (IgM) and IgG antibodies in the serum can be detected and followed. In addition, EBV-related antigen can be quantified in the serum. PCR techniques have been successful in detecting viral DNA in ocular fluids.<sup>41</sup>

## **DIFFERENTIAL DIAGNOSIS**

The diagnostic entities that may mimic EBV chorioretinitis include presumed ocular histoplasmosis syndrome (POHS), recurrent multifocal choroiditis, multiple evanescent white dot syndrome (MEWDS), acute retinal pigment epitheliitis, and birdshot choroidopathy.

## **TREATMENT AND OUTCOME**

In general, EBV-related chorioretinitis appears to be fairly self-limiting. For severe systemic disease, valacyclovir therapy may be of some value.<sup>42</sup>

# Nonherpetic Viral Infections: West Nile, Chikungunya, Zika, Ebola, HTLV 1, Measles, Rubella

7.5

Angela P. Bessette, Sunil K. Srivastava

**Definition:** Nonherpetic viral intraocular inflammations include a diverse group of viral infections—those transmitted by mosquitos or body fluids or nasopharyngeal secretions. Some of these are evolving infectious uveitides; Ebola, chikungunya, and Zika viruses induced ocular inflammations. Well-established uveitis entities are those caused by West Nile virus, human T-cell lymphotropic virus type 1 (HTLV 1), measles, and rubella.

## Key Features

- West Nile virus is a single stranded RNA virus of the *Flaviviridae* family. Its ophthalmic presentations are uveitis and multifocal round and creamy chorioretinal lesions.
- Chikungunya is a single stranded RNA virus of the *Togaviridae* family, and its ocular manifestations are retinitis, uveitis, optic neuritis, conjunctivitis, scleritis, and epithelial keratitis.
- Zika virus is a neurotropic flavivirus; its clinical presentations are microcephaly, optic disc anomalies, uveitis, and chorioretinal changes.
- Ebola virus is a member of *Filovirida*, known to cause severe hemorrhagic fever. Its ophthalmic manifestations are subconjunctival hemorrhage, uveitis, and retinitis.
- HTLV 1 is a retrovirus, and it is endemic in southwest Japan, the Caribbean, and Central and South America. Ophthalmologically it presents with intermediate uveitis, retinal phlebitis, and T-cell leukemia or lymphoma.
- Measles virus is a paramyxo RNA virus. Its congenital infection manifests as cataract and pigmentary retinopathy. Acquired infection presents with retinopathy, small hemorrhages, stellate macula lesions, and optic disc swelling.
- Rubella virus belongs to *Rubivirus* and family of *Togaviridae*. Congenital infection presents with a salt-and-pepper fundus appearance. Acquired infections manifests with conjunctivitis, keratitis, iritis, and in some with features of Fuchs' cyclitis.

## WEST NILE VIRUS

### INTRODUCTION

The West Nile virus (WNV) is a single-stranded, enveloped RNA virus that is a member of the *Flaviviridae* family.<sup>1</sup> Wild birds are the primary natural hosts, and the virus is most commonly transmitted to humans through the bite of the *Culex* mosquito. Only a minority of infected individuals experience symptoms, which most often include fever, malaise, rash, and lymphadenopathy. Less than 1% of those infected experience neuroinvasive disease, including neurological deficits, aseptic meningitis, and, rarely, death.<sup>2</sup>

### EPIDEMIOLOGY

WNV has been a known cause of febrile illness and sporadic encephalitis since its discovery in 1937 in Uganda, but it was not detected in the

Western Hemisphere until an outbreak of encephalitis in New York City in 1999.<sup>3,4</sup> Subsequently, it spread rapidly across the continental United States and remains the most common cause of neuroinvasive arboviral disease in the United States.<sup>3,5</sup> In 2015, 2175 cases of WNV were reported to the Centers for Disease Control and Prevention (CDC).<sup>5</sup>

## OCULAR MANIFESTATIONS

Ocular manifestations include chorioretinitis with lesions either scattered or in linear arrays, uveitis without focal chorioretinal lesions, occlusive retinal vasculitis, congenital chorioretinal scarring, and optic neuritis.<sup>1</sup> The classic chorioretinal lesions of WNV are round, multifocal, and creamy. Multimodal imaging of the active lesions will show central hypofluorescence with surrounding staining on fluorescein angiogram (FA), dense hypocyanescence corresponding with the center of the lesion on indocyanine green (ICG) angiography, hyperautofluorescence on fundus autofluorescence (FAF) imaging, and deep retinal hyperreflective lesions extending from the outer nuclear layer to the retinal pigment epithelium (RPE) on optical coherence tomography (OCT).<sup>4</sup> Patients usually have a mild vitritis and variable anterior chamber inflammation. The lesions generally become more pigmented over time (Fig. 75.1) and have a benign, self-limited course although there are reports of permanent visual deficits in patients with subfoveal lesions or those who later develop choroidal neovascular membranes.<sup>1,2</sup> Patients with optic neuritis and occlusive retinal vasculitis are more likely to have permanent visual deficits.<sup>2</sup>

## DIAGNOSIS

WNV is diagnosed by detection of WNV-specific IgM in the serum or cerebrospinal fluid (CSF). It is important to remember that there is cross-reactivity amongst flaviviruses and patients who have been recently vaccinated for yellow fever may have a false-positive result.<sup>1</sup>

## TREATMENT

Currently, there is no treatment for WNV other than supportive measures. Anterior segment inflammation has been treated successfully with topical corticosteroids and cycloplegic agents. Case reports have demonstrated good anatomic response to intravitreal bevacizumab for the treatment of macular edema and late choroidal neovascularization.<sup>6,7</sup>

## CHIKUNGUNYA

### INTRODUCTION

Chikungunya is a single-stranded RNA virus from the *Togaviridae* family that is transmitted by the *Aedes* mosquito.<sup>8,9</sup> Chikungunya fever is characterized by fever, severe arthralgia, and skin rash.<sup>8</sup> The illness is generally self-limited, but severe complications can occur, especially in the elderly and those with chronic medical problems.<sup>10</sup>

### EPIDEMIOLOGY

Chikungunya virus has long been endemic in Africa, Southeast Asia, and parts of the Indian subcontinent.<sup>9</sup> The first report of local transmission of

**Fig. 7.5.1** An 87-Year-Old Woman Presented With Encephalitis and Tested Positive for West Nile Virus. (A) The healed lesions are seen several months after infection. (B) The lesions have variable pigmentation and atrophy, many with central hyperpigmentation surrounded by atrophy. (Courtesy Sunil Srivastava, MD.)

**Fig. 7.5.2** A 43-Year-Old Man With Bilateral Chikungunya Retinitis Characterized by Bilateral Retinal Whitening and Hemorrhages in the Posterior Pole. (Courtesy Padmamalini Mahendradas, DO, DNB.)

chikungunya in the Western Hemisphere was not until December 2013.<sup>10</sup> Now it is endemic in tropical areas of the Americas, including Central America and the Caribbean.<sup>9</sup>

## OCULAR MANIFESTATIONS

A wide array of ocular manifestations have been associated with chikungunya virus, including nongranulomatous anterior uveitis, optic neuritis, retinitis, panuveitis, choroiditis, conjunctivitis, episcleritis, scleritis, and epithelial keratitis.<sup>9</sup> Ocular manifestations may be present during or occur several weeks after the febrile illness, and iridocyclitis and retinitis are the most common ocular manifestations associated with chikungunya virus.<sup>11</sup> Chikungunya retinitis is characterized by minimal vitritis, retinal hemorrhage, retinal whitening, and edema, most commonly in the posterior pole (Fig. 7.5.2).<sup>11</sup>

## DIAGNOSIS

During the first 7 days of infection, serum polymerase chain reaction (PCR) is the preferred method of diagnosis. After the first 7 days of infection, virus-specific IgM antibodies can be detected in serum.<sup>12</sup>

## TREATMENT

Currently, there is not an approved antiviral agent with activity against chikungunya, so the treatment remains largely supportive.<sup>9,11</sup> Anterior uveitis may be treated with topical corticosteroids.<sup>9</sup> Some reports suggest that systemic corticosteroids are beneficial in the treatment of optic neuritis, posterior uveitis, and keratouveitis, whereas others describe resolution of retinitis with systemic acyclovir and corticosteroids.<sup>9,11</sup> More studies are needed to determine whether such treatments are effective in improving the visual outcome.

## ZIKA

### INTRODUCTION

Zika virus is a neurotropic flavivirus transmitted most frequently by the *Aedes aegypti* mosquito.<sup>13,14</sup> Infected mothers can transmit the virus to fetuses, and sexual transmission has also been confirmed. Viral RNA has been identified in the sperm of infected men, although the duration of the risk of sexual transmission after infection is unknown.<sup>15</sup> Infection is characterized by fever, arthralgia, and rash.<sup>13</sup>

### EPIDEMIOLOGY

Zika virus was first identified in humans in Nigeria in 1953.<sup>15</sup> The first reported outbreak outside of Africa was not until in 2007 on Yap Island in the Federated States of Micronesia.<sup>14,15</sup> In 2015, an outbreak in Brazil reached epidemic proportions, and 6 months later an increase in the number of infants born with microcephaly alerted health officials to the association between maternal Zika infection and congenital central nervous system malformations.<sup>14,15</sup>

### OCULAR MANIFESTATIONS

Many ocular abnormalities have been documented in infants with microcephaly secondary to presumed congenital Zika infection. Changes in the vasculature, including tortuosity and hemorrhagic retinopathy; optic disc anomalies, including hypoplasia, severe cupping, and pallor; and macular changes, including pigment mottling, torpedo-like maculopathy, and sharply demarcated circular areas of chorioretinal atrophy; have all been described.<sup>14,16,17</sup> Infants with smaller cephalic diameters and those whose mothers were symptomatic in the first trimester are more likely to have ocular abnormalities.<sup>14</sup>

Infected adults may also have ocular involvement. Over 50% of infections are associated with nonpurulent conjunctivitis.<sup>15</sup> Case reports have also described anterior and posterior uveitis associated with Zika infection. Merle et al. described two patients with confirmed Zika infection who presented with bilateral hypertensive acute anterior uveitis. Zika RNA was detected in the aqueous humor of one of the four affected eyes.<sup>18</sup> Furtado et al. reported a case of bilateral normotensive anterior uveitis associated with Zika infection. Viral RNA was detected in the aqueous humor of one of the affected eyes.<sup>19</sup> Posterior involvement has also been reported in the form of a mild vitritis with mid-peripheral yellow-white chorioretinal lesions in one patient and unilateral acute idiopathic maculopathy in two others.<sup>13,20,21</sup>

### DIAGNOSIS

Within the first 7 days of infection, viral nucleic acid can be detected in serum by RT-PCR. After the first week, IgM antibodies can be detected by enzyme-linked immunosorbent assay (ELISA).<sup>15</sup>

### TREATMENT

Treatment is supportive and guided by symptoms. Anterior uveitis has shown response to topical corticosteroids and elevated intraocular pressure can be treated with aqueous suppressants.<sup>18,19</sup> Patients with acute idiopathic maculopathy have shown complete recovery without treatment.<sup>13,21</sup>

## EBOLA

### INTRODUCTION

Ebola virus is a member of the family *Filoviridae*.<sup>22</sup> It causes a severe hemorrhagic fever characterized by a maculopapular rash, fever, vomiting, diarrhea, myalgias, respiratory symptoms, and abdominal pain. It causes severe laboratory abnormalities, including transaminitis, prolonged clotting times, leukopenia, and thrombocytopenia. It is fatal about 50% of the time due to hemorrhagic complications and multiple organ failure.<sup>22,23</sup> Wild animals, particularly fruit bats, are the natural virus hosts, and human infection occurs via close contact with the blood or bodily fluids of infected animals. Ebola is highly contagious, and human-to-human transmission occurs through direct contact with the blood or bodily fluids of infected individuals.<sup>23</sup>

## EPIDEMIOLOGY

Ebola virus first appeared in humans in 1976 in two simultaneous outbreaks in South Sudan and the Democratic Republic of Congo.<sup>23</sup> An outbreak in West Africa in 2014 was the largest to date and affected Guinea, Liberia, and Sierra Leone most severely.<sup>23</sup>

### OCULAR MANIFESTATIONS

During acute infection, conjunctival injection and subconjunctival hemorrhages may occur.<sup>22</sup> Uveitis is the most common ocular complication during convalescence and may include anterior, intermediate, posterior, and panuveitis.<sup>22,24,25</sup> Ebola virus has been detected in the aqueous humor of a patient 14 weeks after the onset of infection and 9 weeks after the clearance of viremia.<sup>26</sup> That patient developed a unilateral hypertensive anterior uveitis that rapidly progressed to scleritis and panuveitis, which was treated successfully with topical, periocular, and oral corticosteroids.<sup>26</sup> Uveitis relapses have been documented up to 13 months after blood tests negative for Ebola virus, suggesting a need for long-term monitoring in Ebola survivors.<sup>24</sup>

### DIAGNOSIS

Diagnosis of Ebola is made by detection of viral RNA, IgM antibodies, or viral antigens.<sup>22</sup> Samples from infected patients are an extreme biohazard risk and must be handled in a biosafety level 4 laboratory.<sup>22,23</sup>

### TREATMENT

There is no proven treatment for Ebola virus. Thus treatment is largely supportive and consists of oral and intravenous hydration in addition to managing end-organ complications.<sup>23</sup> Uveitis has been successfully treated with topical, oral, and periocular corticosteroids and cycloplegic agents.<sup>22</sup>

## HUMAN T-CELL LYMPHOTROPIC VIRUS TYPE 1

### INTRODUCTION

Human T-cell lymphotropic virus type 1 (HTLV-1) was the first retrovirus discovered to cause human disease.<sup>27</sup> Perinatal infection with HTLV-1 is considered a risk factor for adult T-cell leukemia and for a degenerative neurological disorder known as tropical spastic paraparesis.<sup>28</sup>

### EPIDEMIOLOGY/PATHOGENESIS

In certain populations, infection with HTLV-1 is considered endemic, such as in areas of southwest Japan. It is also common in the Caribbean and parts of Central and South America.<sup>27</sup> It is transmitted via breastfeeding, sexual contact, or blood exposure.<sup>28</sup> In one study, 0.79% of people tested were seropositive for the HTLV antigens.<sup>29</sup> The interaction of HTLV-1-disregulated cells with various kinds of normal lymphocytes and vascular endothelial cells may determine the type of HTLV-1-associated disease manifestation.<sup>30,31</sup>

### OCULAR MANIFESTATIONS

Ocular manifestations include vitritis and uveitis/vasculitis.<sup>32</sup> Most patients present with an intermediate uveitis with prominent vitreous opacities.<sup>27</sup> A vasculitis composed of gray-white granular deposits scattered on the retinal veins and arteries may be characteristic of HTLV-1-associated retinal disease. Other manifestations include T-cell conjunctival and intraocular lymphomas, interstitial keratitis, Sjögren's syndrome, optic neuritis, and retinal choroidal degeneration.<sup>33</sup> A single episode of uveitis with resolution over a few weeks occurs in the majority of patients. Only a few patients suffer poor visual outcomes from either corticosteroid-induced cataracts or a retinal choroidal degeneration. HTLV-1 associated lymphomas are aggressive, and therapy is often not successful.

### DIAGNOSIS

Tests for viral DNA, including PCR techniques, have proved the presence of the HTLV-1 virus. Serum antibodies against the HTLV-1 proteins have also been used to make the diagnosis of systemic HTLV-1 infection.

## TREATMENT

The intraocular inflammation may respond to corticosteroid therapy.<sup>34</sup> Systemic disease is difficult to treat but may respond to chemotherapy, daclizumab, and antiretroviral treatment with 5-azacytidine.<sup>35,36</sup>

## MEASLES VIRUS

### INTRODUCTION

The measles virus is another RNA virus classified as a paramyxovirus. Infection with the virus is usually self-limited but can be associated with subacute sclerosing panencephalitis (SSPE).

### EPIDEMIOLOGY/PATHOGENESIS

The virus is transferred by nasopharyngeal secretions to the respiratory tract or conjunctiva of susceptible patients. The virus is highly contagious and is typically contracted in childhood. Congenital infections can occur. Prenatal transmission in the first trimester may cause abortion; infection later may result in premature birth or malformations such as cardiomyopathy, cataract, deafness, and pigmentary retinopathy.

### OCULAR MANIFESTATIONS

The ocular manifestations of congenital infection include cataract and pigmentary retinopathy.<sup>37</sup> The most common ocular manifestations of acquired infection are a self-limited keratitis or conjunctivitis. Retinopathy can occur with acquired measles infections. During the acute stages of retinal involvement, the fundus vessels may appear attenuated. There may be diffuse retinal edema associated with optic disc swelling, small hemorrhages, and stellate macular lesions. Irregular, flat, depigmented areas may also appear with some decline in vision. As the retinopathy resolves, a secondary pigment retinopathy with a salt-and-pepper appearance may occur. Retinal findings associated with SSPE include macular edema, pigment epithelial abnormalities, choroiditis, whitish retinal infiltrates, serous macular detachments, areas of retinal depigmentation, and optic neuritis.<sup>38–41</sup>

Macular retinitis may occur first and then the neurological finding of SSPE may result. Early recognition may allow earlier serological testing for SSPE and allow an earlier diagnosis of this disease.<sup>42</sup>

### DIAGNOSIS AND ANCILLARY TESTING

Fluorescein angiography may demonstrate a diffuse leakage associated with retinal edema or increased transmission of choroidal fluorescence related to the pigment epithelial disease. There may be vascular occlusions, retinal pigment epithelial disturbances, and cystic areas of hyperfluorescence. Serological tests for measles virus include complement fixation, enzyme immunoassay, immunofluorescence, and the hemagglutination

inhibition test.<sup>39</sup> In addition, PCR techniques may be used for detecting viral RNA.<sup>43</sup>

## PATHOLOGY

Histological specimens have been documented in patients who have suffered from SSPE. Histologically, there are areas of focal retinal necrosis with invasion of pigment-laden macrophages. The retinal pigment epithelium may show patchy areas of loss. Intranuclear inclusions can be seen in the nuclear layers of the retina.<sup>39</sup>

### TREATMENT

Measles retinopathy may result in the onset of acute blindness a few weeks following the measles rash and in general resolving over the following months. No therapy exists for measles-related retinopathy.

## RUBELLA VIRUS

The ophthalmic manifestations of rubella virus are similar to those of measles virus infections, and both can be seen in congenital and acquired forms. The congenital rubella retinitis may present as a salt-and-pepper fundus appearance. Ophthalmic manifestations include conjunctivitis, keratitis, and iritis. A retinitis may appear and can be associated with exudative detachments of the retina and retinal pigment epithelium.<sup>44,45</sup>

### SUMMARY

Multiple viruses can cause intraocular inflammation. Many of them can cause decreased vision and can have devastating long-term effects. Ocular manifestations of other viral infections are being discovered. New diagnostic techniques such as PCR may allow testing for the presence of a viral cause for some of the idiopathic intraocular inflammations.

## Syphilitic and Other Spirochetal Uveitis

## 7.6

Julie H. Tsai

## SYPHILITIC UVEITIS

**Definition:** Intraocular inflammation as a result of infectious and/or immunologically mediated responses to *Treponema pallidum*.

## Key Features

- Intraocular inflammation typically associated with systemic manifestations.
- Latent disease associated with intraocular/systemic findings.

## Associated Features

- Conjunctival gummas and chancres.
- Episcleritis or scleritis.
- Cataracts (congenital or acquired).
- Secondary glaucoma.
- Interstitial keratitis.
- Light-near dissociation (Argyll–Robertson pupil).
- Retinitis, typically placoid.

## INTRODUCTION

Infection with the spirochete *Treponema pallidum* (*T. pallidum*) results in multiple systemic and ocular manifestations. This occurs primarily via sexual contact, with secondary routes of infection including contact with an infectious lesion, maternal–fetal transmission, and transfusions. Historically, syphilis carried significant social stigma and was associated with high morbidity and mortality. After penicillin became widely available, a steep decline in the incidence of infection was noted, but bacterial resistance, high-risk sexual behavior, infection with human immunodeficiency virus (HIV), and changing socioeconomic factors have all contributed to a recent resurgence of disease worldwide.<sup>1,2</sup>

Ocular manifestations, while uncommon, are typically associated with neurosyphilis, which can occur early or late in the course of infection.<sup>3</sup> Uveitis is the most common sign, ranging from 0.7% to 16.4% of patients with secondary or tertiary syphilis.<sup>4</sup> The clinical presentation is diverse, with various inflammatory presentations such as iritis, chorioretinitis, vitritis, and panuveitis.<sup>1,5</sup>

## EPIDEMIOLOGY AND PATHOGENESIS

The World Health Organization (WHO) reported an estimated incidence of 5.6 million new cases of venereal syphilis and a prevalence of 18 million cases worldwide in 2012.<sup>6</sup> Recent outbreaks in Europe and North America have been seen in areas where individuals often have multiple sexual partners and in populations of men who have sex with men (MSM). Specifically, between 2015 and 2016, new syphilis cases increased 176% in the United States (US) and 12% in the United Kingdom.<sup>2,7</sup> As of 2018, the total reported case counts in the US are the highest to date since 1994, and increased 176% between 2015 and 2016 alone, with 58.1% of cases attributed to the subpopulation of MSM.<sup>2</sup>

The pathogenesis of syphilitic disease is complex and is initiated as the bacteria enter the body through intact mucosa or areas of abraded skin. Local invasion of the tissues occurs with dissemination via blood and the lymphatic system. Microscopically, lymphocytic infiltration is seen, either diffuse or focal, surrounding the blood vessels of affected organs along

with chronic granulomatous inflammation including epithelioid histiocytes and multinucleated giant cells. Mononuclear cells, sensitized T lymphocytes, macrophages, and plasma cells can also be seen. It is likely that this inflammation and the resulting adaptive immune response cause the tissue destruction characteristic of syphilis, as the bacteria do not produce an intrinsic toxin.

Local antibodies are also produced against the lipid, protein, and lipoprotein components of *T. pallidum*. The majority of bacteria are eradicated by opsonization and engulfed by macrophages. Those organisms resistant to phagocytosis may persist locally at the site of inoculation. Dissemination can occur despite the development of the humoral and cellular response, and without treatment, the bacteria can persist in the human host for decades, resulting in continued transmission and end organ damage.

## OCULAR MANIFESTATIONS

Ocular findings play a critical diagnostic role in the evaluation and treatment of infection. Keratic precipitates, iritis, vitritis, focal retinitis, papillitis, periphlebitis, outer retinitis, and exudative retinal detachments have been described among HIV-positive and HIV-negative patients.<sup>8</sup> The most common forms of uveitis in syphilitic infection are nonspecific iritis and iridocyclitis, and these may manifest as granulomatous or nongranulomatous inflammation. Dilated iris capillaries (roseola) have been described as a distinctive feature and may result from obliterative endarteritis.

Chorioretinitis is also common and presents in various ways. Vitritis, vasculitis, macular edema, exudative retinal detachment, uveal effusion, central retinal vein occlusion, choroidal neovascularization, retinal necrosis, and neuroretinitis have all been described (Fig. 7.6.1).<sup>9–11</sup> In patients with HIV, placoid lesions ranging in color from yellow to gray have been described in juxtapapillary locations as well as adjacent to the macula. This condition is also termed acute syphilitic posterior placoid chorioretinitis.<sup>5,12</sup> These lesions are often atrophic in the center and flat. Fluorescein angiography reveals early hypofluorescence and late stain of the lesions, termed “leopard-spot” hypofluorescence (Fig. 7.6.2). This finding is also labeled acute syphilitic posterior placoid chorioretinitis. It is not pathognomonic of HIV-related syphilitic retinitis, however, and can be seen in infected

Fig. 7.6.1 Retinitis in a Patient With Positive Serology for Syphilis.

**Fig. 7.6.2** “Leopard Spot” Hypofluorescence in the Macula of a Patient With Neurosyphilis. (Courtesy Chao et al. Syphilis: reemergence of an old adversary. Ophthalmology 2006;113:2074–9.)

individuals with normal immunity. Dense vitritis may also be the only presenting sign of infection in HIV-positive patients.<sup>13,14</sup>

Other ocular structures may also be affected, including the cornea, conjunctiva, sclera, and optic nerve. Syphilitic interstitial keratitis in the corneal stroma is probably the best known presentation and often results from congenital disease. In acquired infection, stromal inflammation is seen in the peripheral cornea, with marginal infiltrates observed in the anterior corneal stroma. Anterior uveitis may also be present. Deep stromal vascularization anterior to Descemet's membrane is the most distinctive feature of interstitial keratitis. Ridges or scrolls of Descemet's membrane may also be noted (Fig. 7.6.3). Once the infection is treated and the inflammation resolved, corneal scarring and thinning are often the end result, and the inactive neovascular vessels (i.e., “ghost” vessels) may be difficult to identify due to surrounding stromal scarring (Fig. 7.6.4).

Conjunctival involvement may occur in any stage. A chancre may develop, similar to lesions seen elsewhere on the body. The ulcerative

**Fig. 7.6.4** Ghost Vessels in Syphilitic Interstitial Keratitis. (Courtesy Krachmer JH, Palay DA. Cornea atlas. 2nd ed. Elsevier; 2006.)

lesion often has a rounded edge and is surrounded by conjunctival injection. Discharge is rare, and local irritation caused by the lesion is the most common complaint. A mild, nonspecific papillary reaction associated with secondary syphilis may be easily overlooked. Episcleral and scleral involvement is generally associated with conjunctival disease, with isolated cases uncommon at any stage of infection. Necrotizing conjunctivitis with marked pain and injection may be seen in tertiary disease.

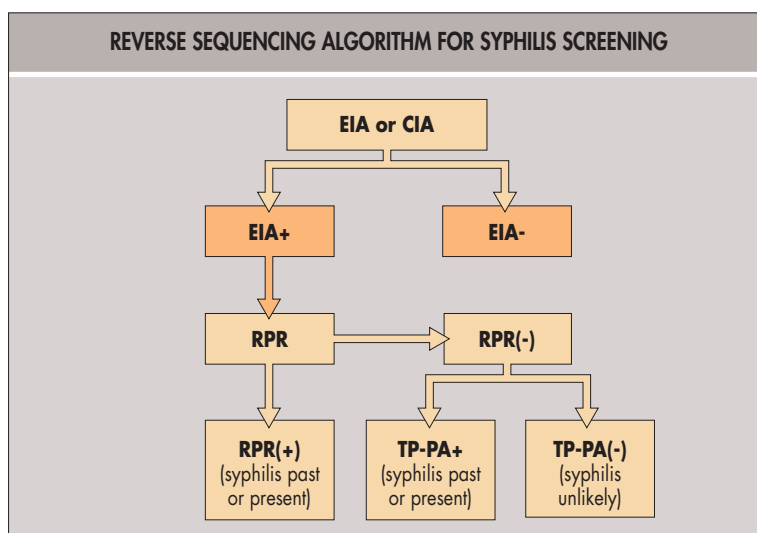

Other ocular manifestations include cataract, glaucoma, and pupillary abnormalities. Cataracts may be found in congenital or acquired disease, but the finding itself is not a distinctive feature. Glaucoma in syphilis is often secondary to uveitis and may also occur in either congenital or acquired infection. It is postulated that failure to develop a mature anterior segment and angle in infants with congenital or acquired disease may result in narrow-angle glaucoma in later life. The Argyll–Robertson pupillary abnormality, seen in neurosyphilis, is a classic finding. The patient exhibits anisocoria, often with irregularly shaped pupils, and clinical testing may reveal light-near dissociation. Horner's syndrome and internuclear ophthalmoplegia may also be observed. Late neurosyphilis may cause general paresis and tabes dorsalis.

## DIAGNOSIS

The clinical presentation of syphilitic uveitis is extremely variable and thus the disease has acquired the nickname “the great masquerader.” A high level of clinical suspicion is required, and appropriate laboratory studies are necessary to confirm the diagnosis and rule out other disease entities. The gold standard remains the use of dark field microscopy or immunofluorescent staining of mucocutaneous lesions to demonstrate the presence of live organisms. Diagnosis can be confirmed as early as 10–20 days post-contact, even before seroconversion. The tests are highly specific but not very sensitive for widespread use.

Two different types of antibody tests are utilized in serological testing: nontreponemal tests, which detect antibody to cardiolipin cholesterol antigen, and treponemal tests, which detect antibodies against treponemal antigens. In the past, two commonly used nontreponemal tests are the Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin (RPR) tests. These were best suited for general screening in a population with a low prevalence of syphilis. The nontreponemal tests quantitatively measure antibody production and can determine cases of active infection. They can also be used to monitor treatment efficacy as the titers decrease with appropriate therapy.

Positive results from the nontreponemal tests were then verified using treponemal tests. These include the fluorescent treponemal antibody absorption tests (FTA-ABS) and microhemagglutinin assay for *T. pallidum* (MHA-TP). They may be used initially in individuals with a high probability of disease. The treponemal tests document cases of tertiary or latent syphilis and show evidence of previous exposure even if screening tests are negative. Once the treponemal test is positive, the patient generally remains positive for life. These tests are more specific than the nontreponemal tests and may be just as sensitive, but their expense and

**Fig. 7.6.5 Reverse Sequencing Algorithm for Syphilis Screening.** An immunoassay for treponemal antibodies is used to initiate the testing protocol. Negative results rule out syphilis, but a positive result is followed by a nontreponemal quantitative test. A positive nontreponemal test is considered diagnostic of syphilis infection, either past or present. Further confirmation can be performed with a sensitive and specific treponemal agglutination test. *CIA*, Chemiluminescence immunoassay; *EIA*, enzyme immunoassay; *RPR*, rapid plasma regain; *TP-PA*, treponemal pallidum particle agglutination. (Adapted from the Centers for Disease Control and Prevention. Reverse sequence syphilis screening webinar [Internet] [cited 6 Jan 2017]. Available from: <http://www.cdc.gov/std/syphilis/Syphilis-Webinar.htm>.)

proportionate increase in false positives reduce their utility as a screening test, especially in a low-risk population.

Currently, in cases of suspected syphilitic uveitis, newer treponemal tests, such as enzyme immunoassays (EIA) and chemiluminescence assays (CIA), utilizing specific treponemal antigens have been approved by the Food and Drug Administration (FDA) and are recommended by the Centers for Disease Control and Prevention (CDC) as initial screening tests for syphilis (<http://www.cdc.gov/std/syphilis/Syphilis-Webinar.htm>). These new tests have specific IgM and IgG antitreponemal antibodies for the detection of early and late syphilis, respectively, and remain positive for life. They have high sensitivity and low specificity for diagnosis, and false-positive test results may be associated with certain infections (e.g., Lyme disease, leptospirosis, malaria) and medical conditions (e.g., autoimmune disorders, intravenous drug use, pregnancy). Given these diagnostic limitations, a confirmatory treponema particle agglutination test would be submitted (Fig. 7.6.5). This new “reverse sequence” algorithm would capture those individuals with either very early disease or late findings (e.g., neurosyphilis with ocular complications) who would be positive by treponemal-specific testing but negative by RPR.

In individuals infected with HIV, false positives and persistent high titers may occur in nontreponemal testing due to polyclonal B cell activation, thus making it difficult to assess the efficacy of treatment. Treponemal testing is also suspect in the setting of abnormal serological response to infection.<sup>15</sup> False-negative tests may occur due to insufficient production of antibody to bacterial proteins or an overall lack of immunoreactivity. With such atypical presentations of syphilitic uveitis in these cases, a high level of suspicion for infection is required.

In cases of neurosyphilis, the CDC recommends the use of cerebrospinal fluid (CSF)-VDRL testing for establishing the diagnosis if nontreponemal and treponemal testing is negative. The use of CSF-FTA-ABS is still controversial, as the test is often too sensitive. CSF-VDRL has an advantage over CSF-FTA-ABS in cases requiring differentiation of current active infection from past infection, though none of the tests are absolute for diagnosis of neurosyphilis. Leukocytosis and elevated protein concentrations are often present for more than a year in those individuals with neurological symptoms. Treatment for presumed neurosyphilis is then warranted, even if test results are negative.

## DIFFERENTIAL DIAGNOSIS

The possible differential diagnoses for syphilitic uveitis are protean (Box 7.6.1). A high degree of clinical suspicion is necessary to make the diagnosis, and serological confirmation is required. The most critical diagnosis to

### BOX 7.6.1 Differential Diagnosis in Ocular Syphilis

Toxoplasmosis  
 Rubella  
 Cytomegalovirus (CMV)  
 Human immunodeficiency virus (HIV)  
 Herpes simplex virus (HSV)

 HLA-B27-related uveitis  
 Primary intraocular lymphoma  
 Sarcoidosis  
 Tuberculosis  
 Idiopathic uveitis

make may be acute syphilitic posterior chorioretinitis, and differentiating it from acute posterior multifocal placoid pigment epitheliopathy (APMPPE) and atypical serpiginous choroidopathy is of utmost importance, due to the possible use of systemic immunosuppressive therapy for treatment of these conditions.

## SYSTEMIC ASSOCIATIONS

The three clinical stages are accompanied by characteristic clinical findings. The chancre, an ulcerative lesion occurring at the site of inoculation, is pathognomonic for the primary stage of infection. It may be associated with a flu-like syndrome secondary to the initial bacteremia, though it is rare. The chancre spontaneously heals within 2 weeks, during the organism's incubation period, which ranges from 3 days to 3 months, with an average of 3 weeks.

Several weeks after contact, systemic manifestations of fever, malaise, lymphadenopathy, and mucocutaneous eruptions can be seen. This marks the second stage of infection and occurs in 60%–90% of patients. One third of these individuals may also have primary lesions. Up to 25% of patients with early syphilis, defined as primary, secondary, or early latent stages of disease of less than 1-year duration, develop neurological symptoms.

The tertiary stage is often associated with late complications. Focal inflammatory lesions (gummas) may affect any organ, and those in the central nervous system (CNS) may lead to visual field deficits. One third of untreated patients develop tertiary syphilis, and neurosyphilis develops in less than 1%. In HIV-positive patients, necrotizing encephalitis may occur and is usually more aggressive than the findings seen in tertiary syphilis (e.g., tabes dorsalis and general paresis).

## PATHOLOGY

Lymphocytic infiltration, diffuse or focal, surrounds the blood vessels of affected organs in syphilitic uveitis. The iris, ciliary body, and choroid all exhibit these findings along with signs of chronic granulomatous inflammation. Obliterative vasculitis with a predominance of mononuclear and plasma cells may also be seen.

## TREATMENT

Penicillin G is the mainstay of treatment for all stages of syphilis (Table 7.6.1). The treatment is determined by the stage and clinical findings. Sexual partners of the infected patient also need to be evaluated and treated accordingly.<sup>16</sup> For individuals with a penicillin allergy, alternative antibiotics may be used, though they are not as effective. Skin testing and desensitization may be recommended or required, particularly in cases where the patient is concurrently infected with HIV. For patients diagnosed with congenital syphilis, treatment with aqueous penicillin G or procaine penicillin G via intravenous administration is considered the standard of care. Other antibiotics (e.g., ceftriaxone and ampicillin) have been used, but there is currently no optimal therapy for congenital infection. Neurosyphilis requires treatment with penicillin, as there is no effective alternative.<sup>3</sup>

Failure of primary therapy with evidence of tertiary disease prompts further evaluation of the CSF. In HIV-positive individuals, the infection is more aggressive, and abnormalities in serological response and CSF findings make these situations more challenging. The dose and duration of therapy must be sufficient to cure neurosyphilis, regardless of CSF findings.<sup>16–18</sup>

Success with therapy at any stage may be evaluated by improvement in clinical findings and seroconversion or low titers on nontreponemal

TABLE 7.6.1 Recommended Treatment of Syphilis

Stage of Disease	Preferred Treatment	Alternative Treatment
Primary, secondary, or early latent	Benzathine penicillin G 2.4 million units IM, single dose	Doxycycline 100 mg po bid × 2 weeks or tetracycline 500 mg po qid × 2 weeks
Late latent, latent syphilis of unknown duration, tertiary stage, or those who fail primary therapy	Benzathine penicillin G 2.4 million units IM, administered weekly × 3 weeks	Doxycycline 100 mg po bid × 4 weeks or tetracycline 500 mg po qid × 4 weeks
Neurosyphilis	Aqueous penicillin G 3–4 million units IV every 4 hrs × 10–14 days	Procaine penicillin 2.4 million units IM daily × 10–14 days and probenecid 500 mg po qid × 10–14 days

Note: HIV-positive patients should be treated with penicillin at all stages of infection, and those allergic to penicillin should be desensitized and then treated with the full regimen. All patients with tertiary syphilis should have a cerebrospinal fluid analysis and be evaluated for neurosyphilis. Adapted from Workowski KA, Bolan GA, Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines, 2015. MMWR Recomm Rep 2015;64:1–137. Erratum in MMWR Recomm Rep 2015;6:924.

testing. Published criteria describe a four- to eightfold decrease in nontreponemal titers that should occur by 3 and 6 months, respectively. However, these criteria should not be used in monitoring treatment efficacy in the HIV-positive population, as serological testing is often inaccurate. This often justifies the aggressive treatment regimen in these patients.

Adjunct therapy with corticosteroids may be initiated once the infection has been appropriately treated. Residual ocular inflammation may be treated with topical applications, in the cases of anterior uveitis and interstitial keratitis. Systemic medications are often necessary in those individuals with residual scleritis, posterior uveitis, or optic neuritis. Antibiotic therapy should always be administered concurrently with corticosteroid regimens.

## COURSE AND OUTCOME

Early diagnosis and appropriate therapy with antimicrobial agents often determine the outcomes of syphilitic uveitis. With treatment, full visual recovery is common, with improvement in other systemic findings. If untreated, worsening of intraocular inflammation and the development of secondary glaucoma, retinal necrosis, chronic vitritis, and optic atrophy all limit visual potential. Treatment in HIV-positive individuals should be pursued aggressively and initiated early, regardless of CSF findings.

## LYME DISEASE

**Definition:** Multisystem manifestations resulting from tick-borne transmission of *Borrelia burgdorferi*, including ophthalmic, dermatological, neurological, rheumatic, and cardiac findings.

### Key Features

- Primary, or initial, phase with rash noted at the site of the inoculum (erythema chronicum migrans); associated flu-like symptoms can be noted.
- Secondary, or dissemination, phase with systemic signs and symptoms including dermatological, neurological, and cardiac manifestations.
- Tertiary, or late, phase with associated arthritis, meningoencephalitis, polyneuropathies involving both cranial and peripheral nerves, and carditis.

### Associated Features

- Stage 1: Conjunctivitis.
- Stage 2: Cranial nerve palsies, inflammation of optic nerve.
- Stage 3: Inflammation involving cornea, uvea, or retina.

## INTRODUCTION

Lyme disease is a multisystem disorder found in North America, Europe, and Asia. In the United States, the manifestations are caused by infection with *Borrelia burgdorferi* (*B. burgdorferi*), a spirochete transmitted by the Ixodes tick species. The disease can be broken down into stages:

- Stage 1 begins days to weeks after the tick bite and is denoted by the pathognomonic finding of erythema migrans in conjunction with fever, malaise, and arthralgias.

Fig. 7.6.6 Erythema Chronicum Migrans.

- Stage 2 is the phase of dissemination of the spirochete to multiple organs in the days, weeks, or months after infection.
- Stage 3 often occurs after a disease-free period lasting months to years.

Ocular findings can manifest at any stage of infection.

## EPIDEMIOLOGY AND PATHOGENESIS

The disease is named after the town of Lyme, Connecticut, where an outbreak of chronic arthritis in children occurred in 1975. This geographic cluster of cases of oligoarthritis with a seasonal onset was associated with erythema chronicum migrans, severe headaches, and neurological symptoms. Other endemic areas include the Northeast as far south as Virginia; Minnesota, Michigan, and Wisconsin in the Midwest; and Northern California in the West. The pathogenesis of the disease is similar to that induced by *T. pallidum*. The first stage, or early infection, is believed to be caused by spirochetemia. Incubation can occur between 3 and 32 days, and a proinflammatory response occurs in both the innate and adaptive immune systems.<sup>19</sup> This is clinically observed as erythema chronicum migrans, the classic skin rash at the site of the tick bite (Fig. 7.6.6).

The remaining two stages likely result from the immunological response of the host to parasitic invasion.<sup>20</sup> The specific IgM response provides for polyclonal B cell activation and increased levels of circulating immune complexes, while the specific IgG response develops over weeks in response to spirochetal polypeptides and nonprotein antigens. If left untreated, *B. burgdorferi* may survive for several years in the joints, skin, and nervous system.<sup>21</sup> Recent reports seem to support this observation, as in vitro studies indicate that these infectious strains are capable of forming cystic bodies and biofilm aggregates, and current antibiotics have varying effects on these different morphological forms.<sup>22,23</sup>

## SYSTEMIC ASSOCIATIONS

Systemic findings in stage 1 disease begin days to weeks after the tick bite and include erythema migrans, fever, malaise, and arthralgias. A history of tick bite may be absent in 50% of individuals.<sup>24</sup> The dissemination of the spirochete in the second phase occurs within days, weeks, or months after infection. The organism spreads to multiple organ systems, particularly the skin, heart, joints, and nervous system. Neurological manifestations seen

**Fig. 7.6.7 Dense Vitreous Debris in Lyme Disease.**

**Fig. 7.6.8 Moderate Vitritis in Lyme Disease Simulating Intermediate Uveitis.**

at this stage include cranial and peripheral neuropathies and meningoencephalitis.<sup>25</sup> Chronic arthritis and conduction defects may also develop.<sup>21</sup> The lymphocytoma, another skin lesion, may develop, especially on the earlobe or breast, and the initial erythema migrans fades and reappears.<sup>25</sup>

Recurrent manifestations are the hallmark of the third stage and include chronic relapsing arthritis, commonly affecting the knee; acrodermatitis chronica atrophicans, a rash that eventually resolves and leaves atrophy of the skin and underlying structures; and late neurological manifestations such as encephalopathy, demyelination, and dementia.<sup>21,25–27</sup> These findings can occur despite early treatment.

## OCULAR MANIFESTATIONS

Ocular findings in Lyme disease are less prominent compared to the systemic manifestations and can appear at any stage of disease. Conjunctivitis is present in 11% of patients with early stage infection and is considered the most common finding.<sup>28</sup> Nonspecific conjunctival and periorbital inflammations are mild in nature and self-limited. Neuro-ophthalmic complications are associated with stage 2 disease and commonly manifest as ocular motility problems due to cranial nerve palsies, optic neuritis, papilledema, and pseudotumor cerebri in the setting of meningoencephalitis.<sup>26,29,30</sup> Stromal keratitis, episcleritis, and symblepharon formation have been reported in stage 3 disease.<sup>31</sup> Intraocular inflammation often presents as chorioretinitis and vitreous inflammation (Figs. 7.6.7 and 7.6.8).

## DIAGNOSIS

The clinical diagnosis is dependent on the following: appearance of the pathognomonic skin rash (erythema migrans) in a patient with a history of tick bite and/or residence in an endemic region; or a skin lesion with

**TABLE 7.6.2 Differential Diagnosis for Lyme Disease**

Infectious Disorders	Noninfectious Disorders
Syphilis	Sarcoidosis
Tuberculosis	Collagen vascular diseases
Viral keratitis	Vasculitis
Infectious arthritis	Multiple sclerosis
Infectious mononucleosis	Vogt–Koyanagi–Harada disease
Viral encephalitis/meningitis	
Mumps	

### BOX 7.6.2 Criteria for Diagnosis of Lyme Disease

The presence of any one of the following criteria satisfies the diagnosis of Lyme disease.

1. Development of erythema migrans (EM) within 30 days of exposure in an endemic area; size of lesion should be at least 5 cm
2. In the absence of EM, history of exposure to endemic area, with signs involving one organ system and positive laboratory test
3. No history of exposure to endemic area, but with EM as well as involvement of two organ systems
4. No history of exposure to endemic area, but with EM and a positive serology

Adapted from: Case definitions for public health surveillance. MMWR Recomm Rep 1997;46(RR-10):1–55. Recommendations for public health surveillance. MMWR Morb Mortal Wkly Rep 1995;44:590–1.

involvement of two organ systems in those patients without a history of a tick bite or residence in a nonendemic region (Box 7.6.2). Serological testing becomes a useful adjunct, and current CDC recommendations include a two-step process involving an enzyme-linked immunosorbent assay (ELISA) to detect immunoglobulins G and M (IgG, IgM) specific to *B. burgdorferi*. Equivocal results are then tested using Western blot analysis. These results, along with a clinical history suggestive of infection, provide the basis for diagnosis.

## DIFFERENTIAL DIAGNOSIS

The clinician needs to rule out both infectious and noninfectious etiologies with similar clinical presentations, given the various manifestations of Lyme disease. The differential diagnosis is summarized in Table 7.6.2.<sup>32</sup>

## PATHOLOGY

Direct invasion of tissues by the *Borrelia* spirochete can be seen in stage 1. In the later stages, perivascular infiltration of plasma cells has been observed, leading to small-vessel obliteration and vasculitis.

## TREATMENT

Preventive measures in endemic areas include protective clothing, repellents, and acaricides. Tick checks and landscape modifications can reduce exposure. Vaccination is no longer available, and a single dose of doxycycline (200 mg) is no longer recommended for prophylaxis after a documented tick bite. Appropriate antibiotic therapy for a minimum of 10–20 days duration is preferred.<sup>33–35</sup>

The most effective treatment strategy for ocular disease is unclear. Generally, patients benefit from systemic treatment (Table 7.6.3). Topical corticosteroids have been beneficial in treating anterior segment manifestations such as keratitis and episcleritis. Systemic corticosteroids have been utilized in severe cases of ocular inflammation such as vision-threatening uveitis, scleritis, or optic neuritis, but the use may be controversial, as a higher incidence of relapses has been observed.<sup>26</sup> Clinical response may take as long as one year. Inadequate treatment in early stages may lead to relapses and development of late-stage manifestations.<sup>26</sup> Concomitant infections should also be treated if the clinical findings persist despite prolonged antibiotic therapy.

## COURSE AND OUTCOME

The majority of patients respond well to systemic therapy, though posterior uveitis, stromal keratitis, and neurotrophic keratitis are slow to respond to

TABLE 7.6.3 Treatment of Lyme Disease

Early Infection – Local or Disseminated	
Adults	Doxycycline 100 mg orally twice daily for 14–21 days
	Amoxicillin 500 mg orally three times a day for 14–21 days
In case of doxycycline/amoxicillin allergy:	
	Cefuroxime 500 mg orally twice daily for 14–21 days
	Erythromycin 250 mg orally four times daily for 14–21 days
Children	Amoxicillin 50 mg per kilogram of body weight per day in three divided doses for 14–21 days
In case of penicillin allergy:	
	Cefuroxime 30 mg per kg per day in two divided doses for 14–21 days
Neurological and/or Ocular Abnormalities (Early or Late)	
Adults	Ceftriaxone 2 g IV once a day for 14–28 days
	Cefotaxime 2 g IV every 8 hours for 14–28 days
In case of ceftriaxone or penicillin allergy:	
	Doxycycline 100 mg orally 3 times a day for 30 days
Children	Ceftriaxone 75–100 mg per kg per day (maximum 2 g) IV once a day for 14–28 days
	Cefotaxime 150 mg per kg per day in 3–4 divided doses (maximum 6 g) for 14–28 days
Avoid doxycycline in pregnant women.

treatment. Untreated disease can have a relapsing course for several years, with late neurological sequelae similar to those seen in syphilis.

## LEPTOSPIROSIS

**Definition:** A zoonotic infection caused by *Leptospira* species, with effects seen in worldwide distribution.

### Key Features

- Two key phases.
- Leptospiremic: associated with severe myalgia, fever and headache.
- Immune: associated with meningismus, high fever, and central and peripheral neurological manifestations.
- Ocular manifestations are found in the majority of patients and can include subconjunctival hemorrhages, conjunctivitis, and uveitis.

### Associated Feature

- Hemorrhages, renal failure, and jaundice (Weil's disease).

## INTRODUCTION

A severe condition characterized by acute fever, malaise, and uveitis was initially described by Adolf Weil in 1886. The spirochetes of the genus *Leptospira* were discovered as the etiological agents in 1915. This zoonotic infection has a worldwide distribution, with higher incidence in tropical and subtropical climates. Most human infection may be asymptomatic, and there is a wide spectrum of disease presentation that ranges from non-specific febrile illness to multiorgan involvement. Two strains of *Leptospira* exist: *L. biflexia*, a saprophytic strain, and *L. interrogans*, the pathological organism responsible for infection in humans.

## EPIDEMIOLOGY AND PATHOGENESIS

The natural reservoir for pathogenic *Leptospira* is wild animals, especially rodents, but domestic livestock and dogs can also be affected. It is excreted by animal hosts with chronic renal infection, which contaminates soil and water, and humans become accidental hosts on contact with infected urine, tissues, or water. Those at high risk of infection include farmers, veterinarians, abattoir workers, miners, and sewer workers who contract the disease via direct contact. Indirect contact is more common after exposure to wet soil or water through occupational exposure (e.g., rice or taro farming) or

TABLE 7.6.4 Systemic Manifestations of Leptospirosis

Stage	Leptospiremic	Immune
Onset	First week of disease, abrupt onset	Second week
Duration	4–9 days	Undetermined
Manifestations – common	Severe headaches, fever with spikes, chills, myalgia, abdominal pain, skin rash, arthralgias	High fever, meningismus, encephalitis, cranial nerve palsies of sixth, seventh, and eighth cranial nerves, peripheral neuropathy
Manifestations – rare	Jaundice, altered consciousness, cardiac	Spontaneous abortion during pregnancy

TABLE 7.6.5 Ocular Manifestations of Leptospirosis

Anterior	Posterior	Miscellaneous

	Macular edema	
	Retinal hemorrhage	
	Retinal arteritis	

recreational exposures (e.g., adventure tourism in endemic regions). Infection may also be seen in urban centers of developing regions secondary to a lack of sanitation in areas of rapid expansion and growth. Sporadic outbreaks have also been reported in developed countries.<sup>36,37</sup>

The pathogen enters the body through intact mucous membranes, abraded epidermis, or inhalation. The organisms quickly disseminate throughout the body, and a systemic vasculitis ensues that facilitates migration of the spirochetes into organs and tissues. Severe vascular injury can occur, and end organ damage can be seen in the lungs, liver, and kidneys.

## SYSTEMIC MANIFESTATIONS

This broad spectrum of illness may present as subclinical disease, self-limited systemic illness (anicteric, seen in 90% of affected individuals), or severe infection associated with multiorgan involvement (icteric). It is biphasic, with an initial septicemic phase followed by defervescence and the immune phase of illness (Table 7.6.4). The most severe presentation that may develop after the initial phase is Weil's disease, which is characterized by impaired function of the liver and kidneys. The symptoms may progress directly from the acute phase without any improvement prior to the development of more severe symptoms. Mortality rates in these patients range from 5% to 40%.

## OCULAR MANIFESTATIONS

Ocular complications can occur in both the acute and immune phases of illness and can lead to decreased vision and blindness. Conjunctival hyperemia, chemosis, and subconjunctival hemorrhage are most commonly seen in these cases. Changes in the retinal vasculature and the presence of retinal hemorrhages have been reported, along with disc hyperemia and retinal vasculitis.<sup>34</sup> Table 7.6.5 summarizes the ocular findings associated with leptospirosis.

## DIAGNOSIS

Clinical diagnosis of systemic leptospirosis is difficult, given the non-specific symptoms and variable presentations. The diagnostic dilemma extends to the ocular manifestations, where the differential diagnosis for leptospiral uveitis includes both infectious and noninfectious etiologies. Examination alone is unreliable; rather, a high index of suspicion in an endemic region, or in individuals who may have exposure due to socioeconomic or recreational factors, is required. Potential diagnoses of leptospirosis will require laboratory testing for confirmation.

Indirect methods such as the microscopic agglutinin test (MAT) are widely utilized and considered the reference standard assay for serological

**BOX 7.6.3 Differential Diagnosis of Leptospirosis**

Eales' disease	Toxoplasmosis
Endophthalmitis	Leprosy
Tuberculosis	

confirmation of infection.<sup>38,39</sup> However, the sensitivity of these tests is low, particularly on acute phase serum samples, and interpretation of test results is often complicated. Cross-reaction with circulating IgM can confound the results in acute phase samples. The results on acute and convalescent specimens are slightly more sensitive, and overall, these tests are useful adjuncts for confirmation of leptospirosis. Other diagnostic procedures, including a *Leptospira* dipstick test, ELISA, and microscopic slide agglutination tests, have replaced the MAT for more routine use. Polymerase chain reaction (PCR) for the detection of leptospiral DNA may be more sensitive for early identification of *Leptospira* outbreaks.<sup>40</sup>

**DIFFERENTIAL DIAGNOSIS**

The differential diagnosis for leptospirosis is summarized in Box 7.6.3. It is important to note that the manifestations are protean and often mimic influenza-like illnesses, and diagnosis can be difficult, with the exception of Weil's disease.

**TREATMENT**

Systemic disease is effectively treated with antibiotic therapy. Severe infection can be treated with intravenous penicillin (1.5 million units every 6 hours) or ampicillin (0.5–1.0 g every 6 hours) and mild disease with oral doxycycline (100 mg twice daily by mouth), ampicillin (500–750 mg orally every 6 hours), or amoxicillin (500 mg orally every 6 hours).<sup>41</sup> Doxycycline (200 mg given weekly by mouth) can also be used for prophylaxis. Once daily ceftriaxone (1 g intravenous injection) has been shown to be as effective as penicillin. Supportive care for individuals suffering from multiorgan involvement should also be initiated.

Treatment of ocular disease can be accomplished using amoxicillin plus clavulanic acid (1.5 g orally in divided doses each day) and pefloxacin (800 mg daily) for 3 weeks. Corticosteroids, both topical and systemic, may be required for control of intraocular inflammation.

**COURSE AND OUTCOME**

The prognosis for patients with ocular disease is generally good, with one large series reporting that more than 50% of patients regained 20/20 vision.<sup>42</sup> Specifically, anicteric leptospirosis is associated with a better outcome, but Weil's disease is associated with a fatal outcome in 5%–30% of untreated patients.<sup>36,43</sup>

# Tuberculosis, Leprosy, and Brucellosis

Soumyava Basu, Narsing A. Rao

7.7

## Definitions:

- Tuberculosis is a chronic infection caused by *Mycobacterium tuberculosis*. It can involve any part of the eye, though uveitis appears to be most common.
- Leprosy is a chronic granulomatous inflammation of the skin and peripheral nerves, caused by *Mycobacterium leprae*, that affects ocular adnexa and the anterior segment of the eye.
- Brucellosis is a zoonotic disease caused by *Brucella spp.* with a wide range of ocular manifestations.

## Key Ocular Features

### Tuberculous Uveitis

- Mainly presents as posterior or pan uveitis either multifocal choroiditis or multifocal serpiginous-like choroiditis (multifocal, serpiginoid choroiditis), typically involving the posterior pole and midperiphery.
- Retinal vasculitis with or without healed/active chorioretinitis lesions.
- Choroidal tubercles, single or multiple, at the posterior pole.
- Anterior uveitis, mainly granulomatous.

### Leprosy Uveitis

- Chronic granulomatous anterior uveitis with diffuse iris atrophy and miotic pupil.
- Lagophthalmos, hypoesthesia of cornea, exposure keratitis.
- Complicated cataract.

### Brucellosis Uveitis

- Anterior uveitis (low grade), choroiditis.
- Optic neuritis, rarely endophthalmitis.

## Associated Systemic Features

**Tuberculosis** – Pulmonary or extrapulmonary tuberculosis, miliary tuberculosis, positive tuberculin skin test or QuantiFERON-TB Gold test.

**Leprosy** – Few, well-defined (tuberculoid) or widespread, poorly defined (lepromatous) skin macules; peripheral neuropathy, loss of cilia and or eyebrow hair.

**Brucellosis** – History of contact with domestic animals or consumption of unpasteurized milk products, constitutional symptoms, rising titers of *Brucella* antibodies.

## TUBERCULOSIS

### INTRODUCTION

Tuberculosis (TB) is a chronic infection caused by *Mycobacterium tuberculosis* (*Mtb*) characterized by the formation of necrotizing granulomas.<sup>1</sup> The bacteria primarily infect the alveolar macrophages in the lung, from where they are carried to regional lymph nodes and other parts of the body, including the eye. In the eye, TB most often presents as uveitis. The diagnosis of ocular tuberculosis remains largely presumptive and mostly depends on presence of suggestive clinical signs, evidence of past *Mtb* infection, and exclusion of non-TB entities.<sup>2</sup>

## EPIDEMIOLOGY AND PATHOGENESIS

The true prevalence of tuberculous uveitis is difficult to determine, primarily due to the challenges of making an accurate diagnosis of the disease. Most patients with uveitis do not have evidence of systemic TB (active or healed). Microbiological evidence of *Mtb* is rarely found in ocular samples, and the clinical signs of ocular TB are nonspecific and mimic several other infectious and noninfectious uveitis. Not surprisingly, published prevalence of tuberculous uveitis varies widely not only between TB-endemic and nonendemic countries but also between different centers in the same country.<sup>3-4</sup>

The role of *Mtb* in pathogenesis of ocular TB is not clearly understood.<sup>5</sup> Histopathological studies have shown that ocular TB is a paucibacillary infection.<sup>6</sup> A clinically relevant guinea pig animal model of intraocular TB was developed by aerosol delivery of *Mtb*. This model showed ocular lesions mimicking human infection, primarily granulomatous choroiditis.<sup>7</sup>

## OCULAR MANIFESTATIONS

Ocular TB manifests with variable clinical features. It can involve any part of the eye; however, uveitis appears to be a common presentation. The clinical presentation varies between endemic and nonendemic areas. In endemic areas, the disease is more severe and affects all age groups, whereas in nonendemic areas, it is mainly seen in individuals migrated from TB-endemic countries and it appears to be less severe. Moreover, in nonendemic countries it is seen in elderly and immunocompromised individuals.<sup>8</sup> In a patient presenting with granulomatous uveitis in general, the goal in non-TB-endemic regions is to rule out ocular TB, whereas in TB-endemic regions it is to rule out non-TB entities.

### Anterior Uveitis

TB anterior uveitis commonly manifests as granulomatous inflammation with mutton-fat keratic precipitates, posterior synechiae, Koeppe iris nodules at the pupillary margin and iris or angle granulomas.<sup>9</sup> Nongranulomatous anterior uveitis is rare.

### Intermediate Uveitis

Intermediate uveitis commonly presents with chronic, low-grade vitritis with snowball opacities, peripheral vascular sheathing, healed or active peripheral chorioretinitis lesions, and cystoid macular edema.

### Posterior and Pan-Uveitis

These include a wide range of manifestations, such as: retinal vasculitis, multifocal serpiginoid choroiditis in TB-endemic countries such as India, multifocal choroiditis, choroidal tubercles, choroidal or optic nerve head tuberculomas, and subretinal abscess.<sup>10-11</sup>

Choroidal tubercles are the most recognized manifestation of intraocular tuberculosis and result from hematogenous spread of the mycobacteria when a caseous pulmonary lesion erodes blood vessels/lymphatics. These tubercles are generally less than five in number, unilateral or bilateral, grayish white to yellow in color with indistinct borders, and located mostly in the posterior pole (Fig. 7.7.1A). On fluorescein angiography, they are hypofluorescent during the dye transit and hyperfluorescent in the late phase. On healing, the tubercles result in pigmented and atrophic scars. Choroidal tuberculoma generally presents as a solitary subretinal mass that begins as a small, round, whitish lesion gradually becoming yellowish, mimicking a choroidal tumor. Retinal vasculitis is a common manifestation of ocular TB, especially in TB-endemic countries.<sup>12</sup> It presents

**Fig. 7.7.1** (A) Right eye fundus photograph showing choroidal tuberculoma in a patient in treatment for pulmonary tuberculosis. (B) Fundus photograph of right eye showing retinal periphlebitis (*arrow*), associated with active chorioretinitis (*stars*) overlying blood vessels.

**Fig. 7.7.2 Multifocal Serpiginoid Choroiditis in the Right Eye Before and After Treatment.** (A–C) At presentation, clinical photograph showing central scarring and active edges and skip lesions (*arrowheads*). Active choroiditis is represented by hyperautofluorescence (B) and flow void areas in the choriocapillaris layer (C) on OCT angiography. (D–F) Healed lesions characterized by hypoa autofluorescence (E) and “tangled meshwork” of vessels (F, *star*) on OCT angiography (*inset in color photograph*).

as retinal periphlebitis or occlusive vasculitis, often associated with healed or active focal chorioretinal lesions (Fig. 7.7.1B).<sup>13</sup> The occlusive vasculitis can lead to retinal or disc neovascularization, vitreous hemorrhage, and tractional retinal detachment.

Multifocal serpiginoid choroiditis (MSC) is a recently recognized manifestation of TB-associated uveitis in TB-endemic countries.<sup>11,13–15</sup> The multifocal lesions typically show central healing, and active amoeboid margins; some appear healed and others show active choroiditis features (Fig. 7.7.2). Fundus autofluorescence (FAF) is a quick imaging tool for monitoring the clinical course of these lesions. It can vividly display active versus healed lesions (Fig. 7.7.2B and E).<sup>16</sup> More recently, multimodal imaging with simultaneous recording of topographic and tomographic images has helped in combining FAF with optical coherence tomography (OCT) and OCT-Angiography (OCT-A).<sup>17</sup> In active lesions, OCT shows hyperreflectivity

in the outer retina and RPE, whereas OCT-A reveals flow-void areas in the choriocapillaris layer that appear as a tangled meshwork after resolution (Fig. 7.7.2C and F). Rarely, intense inflammatory response in intraocular TB may result in destruction of ocular tissues with a resultant clinical picture of endophthalmitis or rarely panophthalmitis.

## DIAGNOSIS

Ocular TB usually is diagnosed as confirmed (or definitive) or presumed based on the level of evidence supporting tuberculous etiology.<sup>2</sup> Any patient presenting with granulomatous uveitis requires eliciting history of previous exposure to tuberculosis and ruling out other causes of granulomatous inflammation. Such patients require investigations to support clinical diagnosis of tuberculous uveitis. These include:

- Immunological tests; the tuberculin skin test (TST) or interferon-gamma release assay (IGRA).
- Chest radiography (preferably high-resolution computed tomography).
- Intraocular fluid examination to detect *Mtb* DNA by various polymerase chain reactions (PCR).

In general, patients with granulomatous uveitis and positive TST or IGR with the chest imaging findings suggestive of pulmonary TB (active or healed lesions) are diagnosed as presumed intraocular tuberculosis requiring anti-TB treatment. However, the chest imaging can be negative in presumed cases due to the extrapulmonary nature of intraocular tuberculosis. In rare cases, where microbiological (ocular fluid smear or culture) evidence or ocular tissue biopsy evidence of *Mtb* is available, such cases are called confirmed ocular TB. Several uveitis experts consider PCR-positive cases as confirmed, although occasionally the results can be false positive. However, all PCR-positive cases are treated with anti-TB agents in clinical practice when other causes of uveitis have been excluded.

## PATHOLOGY

The characteristic tubercular granulomas show central caseous necrosis surrounded by epithelioid cells, Langerhans giant cells, lymphocytes, and plasma cells.<sup>6,7,18</sup> The granuloma formation is unusual in immunocompromised individuals who mostly show a purulent infection that reveals necrotic and viable neutrophils mixed with macrophages. These lesions contain numerous bacteria.

## TREATMENT

The treatment of TB is complex, and inappropriate management can result in loss of vision and life-threatening consequences and development of drug-resistant organisms. It is advisable to consult a pulmonologist, infectious disease specialist, or internist experienced in the management of systemic tuberculosis. The most commonly employed anti-TB drug regimen consists of isoniazid, rifampicin, pyrazinamide, and ethambutol for the first 2 months, followed by isoniazid and rifampicin for 4–7 months.<sup>19–20</sup> Systemic corticosteroids together with multidrug anti-TB treatment may limit damage to ocular tissues. A unique challenge in management of ocular TB is the high incidence of paradoxical worsening after initiation of anti-TB therapy.<sup>21</sup> This usually occurs in the initial stages of treatment and needs to be distinguished from missed alternative diagnosis, drug-resistant TB, and reinfection. Once confirmed, paradoxical worsening is managed by escalating the corticosteroid dosage while continuing anti-TB therapy.

## LEPROSY

### INTRODUCTION

Leprosy has the highest incidence of ocular complications among all systemic bacterial infections.<sup>22</sup> The ocular complications of leprosy are also largely preventable with early-stage intervention. The disease is caused by *Mycobacterium leprae* and usually spreads by nasal secretions. The disease typically occurs in two stages: the first stage arising from the mycobacterial infection and affecting primarily the skin and upper respiratory tract and the second stage resulting from the cellular immune responses to the leprae organisms that lead to peripheral neuropathy and potentially long-term consequences.

### EPIDEMIOLOGY

As per the World Health Organization (WHO), leprosy has been eliminated from all the 122 countries where it was known to be endemic.<sup>23</sup> This is defined by a prevalence rate of less than 1 per 10,000 population. However, pockets of endemicity still persist in the developing world, especially in Africa and Asia. Current estimates suggest that ocular complications occur in 70%–75% patients with leprosy, with blindness in about 5% of such patients.<sup>24</sup>

### SYSTEMIC MANIFESTATIONS AND PATHOGENESIS OF OCULAR DISEASE

Leprosy has been classified (using the Ridley–Joplin classification) into tuberculoid (TT), lepromatous (LL), and borderline (BT, BB, and BL).

**Fig. 7.7.3 Lepromatous Leprosy Patient With Recurrent Sclerouveitis and Iris Atrophy Due to Autonomic Nerve Fiber Loss.** (Courtesy Sivakumar Rathinam, Aravind Eye Hospital, Madurai, India.)

Tuberculous disease is characterized by one or few skin lesions—well-defined macules or plaques that are scaly, dry, hairless, and anesthetic. Lepromatous disease presents with widespread but poorly defined and erythematous macules, papules, or nodules. Subsequently, peripheral neuropathy involving sensory, motor, and autonomic functions leads to beaded, palpable nerves (most commonly posterior tibial and ulnar) and several forms of disability and deformity.

## CLINICAL PRESENTATION

The most common setting for ocular manifestations is in patients with lepromatous leprosy with ongoing or completed multidrug therapy (MDT). Broadly, these can be subdivided into involvement of the adnexa, ocular surface, and intraocular structures. *Adnexal involvement* includes madarosis or loss of eyebrows and eyelashes due to direct infection of follicles, trichiasis, entropion, ectropion, decreased blinking rate (hypometropic blink), and paralytic lagophthalmos (due to facial nerve palsy in type 1 reaction). Ocular surface involvement manifests as corneal hypoesthesia, corneal nerve beading, dry eyes, exposure keratitis due to lagophthalmos, and secondary infectious keratitis and corneal scarring. Besides these, episcleritis (more common) and scleritis (in type 2 reaction) can also occur. The most common intraocular manifestation is chronic granulomatous iridocyclitis, associated with diffuse iris atrophy, iris pearls (military iris lepromata), miotic pupils, and complicated cataract (Fig. 7.7.3). Retinal and posterior choroidal involvement is extremely rare.

## DIAGNOSIS

The diagnosis of ocular leprosy is based on presence of characteristic systemic disease in high endemic populations and may be confirmed by histopathology of corneal, conjunctival, and subcutaneous skin scrapings.

## TREATMENT

Treatment of leprosy involves rifampicin, dapsone, and clofazimine for a period of 6–12 months. Uveitis requires intensive treatment with topical corticosteroids, while oral corticosteroids may be required in more severe cases in conjunction with antileprosy agents. Phenylephrine is preferred for management of miosis.

## BRUCELLOSIS

### INTRODUCTION

Brucellosis is a zoonotic disease that is mostly spread through ingestion of infected raw milk, dairy products, or raw meat. It is caused by *Brucella* species that are facultative intracellular Gram-negative bacteria. Although

the disease has been eradicated in most countries due to improvements in dairy processing, it remains endemic in parts of the Mediterranean, Middle East, Latin America, and Asia.<sup>25</sup>

## SYSTEMIC MANIFESTATIONS

Brucellosis is a multisystemic disease with both acute (<8 weeks) and chronic (≥8 weeks) manifestations. The incubation period is about 3 weeks. Common presenting symptoms are fever, chills, sweating, myalgia, anorexia, splenomegaly, and diffuse lymphadenopathy. Specific organ systems such as central nervous system, heart, and eye may be involved in 10%–15% cases.<sup>26</sup>

## OCULAR MANIFESTATIONS

As with systemic involvement, brucellosis can have wide range of ocular manifestations. It can be seen in up to a quarter of patients with systemic disease, mostly in the chronic phase of the disease. The most common ocular manifestations are conjunctivitis, anterior uveitis, choroiditis/posterior uveitis, dacryoadenitis, endophthalmitis, and optic neuritis.<sup>27</sup>

## DIAGNOSIS

The diagnosis is based on appropriate history, presence of systemic disease supported by positive serological test (*Brucella* serum agglutination test), and/or positive blood culture (in highly enriched media).

## TREATMENT

Treatment of acute brucellosis requires multidrug treatment with oral doxycycline 100 mg twice daily for 6 weeks along with oral rifampin for 6

weeks or intramuscular streptomycin for 2–3 weeks (preferable). Chronic brucellosis requires antimicrobial therapy with all the three drugs.

## ACKNOWLEDGEMENTS

We would like to acknowledge the previous authors of this chapter: Amod Gupta, Reema Bansal, and Vishali Gupta, for the basic framework of the chapter.

# Bartonella-Related Infectious Uveitis (Cat Scratch Disease) and Whipple's Disease

7.8

Robert C. Wang

**Definition:** Cat scratch disease and Whipple's disease are clinical syndromes characterized by ocular inflammation due to systemic infection from bacillus organisms.

## Key Features

### Cat Scratch Disease

- Most commonly presents as a unilateral granulomatous conjunctivitis with regional lymphadenopathy.
- Typical intraocular presentation includes discrete white retinal or choroidal lesions and the more easily recognizable neuroretinitis with macular star formation.
- More sight-threatening presentation includes retinal vasculitis and vascular occlusions.
- Typically self-limited disease, but more severe presentation may require treatment.

### Whipple's Disease

- Clinical syndrome with gastrointestinal symptoms including diarrhea and weight loss.
- Rare ocular manifestations presenting as a retinal vasculitis and panuveitis, with or without systemic symptoms.
- Multifocal choroiditis and retinitis can be seen as well as retinal vascular occlusions.
- Typically requires antibiotic therapy for up to one year as relapses commonly occur.

## INTRODUCTION

Cat scratch disease has become an increasingly recognized cause of uveitis that has a clinical spectrum ranging from a mild self-limiting disease with neuroretinitis and macular star formation to severe vision loss from retinal vasculitis. Whipple's disease is a less frequent cause of ocular inflammation that is mainly associated with gastrointestinal symptoms including diarrhea. Typical ocular presentation includes panuveitis and vasculitis.

## CAT SCRATCH DISEASE: *BARTONELLA HENSELAE*-ASSOCIATED UVEITIS

## EPIDEMIOLOGY AND PATHOGENESIS

*Bartonella* species are a Gram-negative bacillus that has been associated with a clinical syndrome of a self-limited lymphadenopathy related to a cat scratch or bite or transmission through vectors such as fleas or flies. The causative organism of cat scratch disease (CSD) has been identified as *Bartonella henselae*. The disease has been reported to affect 22,000 patients in the United States but has a worldwide distribution, commonly affecting children and young adults.<sup>1</sup> There is a higher prevalence in the autumn and winter during the seasonal breeding of the domestic cat.

In humans, infection can be relatively asymptomatic or produce symptoms such as fever, malaise, fatigue, and lymphadenopathy. In 25%–60% of cases, an erythematous papule occurs at the site of inoculation with systemic symptoms occurring in the following days to weeks. Typically,

symptoms are self-limited. However, more serious complications can occur, such as splenomegaly, splenic abscess, encephalopathy, granulomatous hepatitis, pneumonia, bacillary angiomatous, and osteomyelitis.<sup>2</sup> Ocular manifestations typically occur following systemic symptoms.

Cat fleas have been identified as a vector for CSD. Other vectors such ticks and biting flies have recently been identified as new potential sources of transmission. Although cats are the main reservoir for *Bartonella henselae*, dogs can be infected and can become accidental hosts. Human infections occur from direct inoculation of open wounds or mucous membranes through scratching or licking.

## OCULAR MANIFESTATIONS

Parinaud's oculoglandular syndrome is the most common presentation of *Bartonella* infection.<sup>3</sup> Patients typically present with a unilateral granulomatous conjunctivitis and regional lymphadenopathy. Patients demonstrate symptoms of unilateral conjunctiva injection, foreign body sensation, and epiphora. Preauricular, submandibular, or cervical lymph nodes are typically affected. Conjunctival epithelium ulcerations and necrosis are commonly seen, producing a purulent discharge.<sup>4</sup>

More sight-threatening presentations of CSD include optic nerve swelling with a complete or partial macular star formation (Fig. 7.8.1). In 1984 Gass termed this appearance *neuroretinitis* to distinguish this entity from primary inflammation of the optic nerve head.<sup>4</sup> Vascular leakage from the optic nerve head results in macular star formation, which may persist for months despite resolution of the neuroretinitis. Additionally, an afferent pupillary defect is typically present in unilateral cases, and a cecentral scotoma is present on visual field testing.

Patients typically present with unilateral decline in vision (20/80) with systemic symptoms present in 67%.<sup>5</sup> Ocular exam typically demonstrates a mild vitritis, with a multifocal retinitis and choroiditis as one of the most common posterior segment findings (Fig. 7.8.2).<sup>3,5</sup> Neuroretinitis is the

**Fig. 7.8.1 Neuroretinitis With Complete Macular Star Formation.** (Courtesy Ehud Zamir MD, the Royal Victorian Eye and Ear Hospital, Melbourne, Australia.)

**Fig. 7.8.2 Discrete "White" Retinal Lesions in Cat Scratch Disease.** (Courtesy Chris Fuller MD, Sam Leiji, COA Berkeley Eye, Houston, Texas.)

most recognizable finding but presents less frequently than the retinal and choroidal lesions. It can present from the overt to a very mild blurring of the disc margins. Macular star formation is seen in approximately 43% of cases.<sup>5</sup> Though macular star formation can be seen at the time of diagnosis, formation can occur 2–4 weeks following the initial onset of neuroretinitis.

Less common posterior segment findings include branch retinal artery and vein occlusion and local serous retinal detachments that can mimic Vogt–Koyanagi–Hamada disease (Fig. 7.8.3).<sup>6</sup> In addition, focal lesions are occasionally associated with angiomas-like proliferation of capillaries.<sup>7</sup> HIV-positive patients can present with a subretinal mass associated with an abnormal vascular network.<sup>8</sup>

## DIAGNOSIS

Diagnosis of CSD is straightforward in the presence of easily recognizable neuroretinitis and macular star formation. Additionally, recognition of isolated discrete white retinal and chorioretinal lesions can lead to a rapid diagnosis in the absence of a macular star or neuroretinitis.

**Fig. 7.8.3 Less Commonly Seen Severe Retinal Vasculitis and Vascular Occlusion in Cat Scratch Disease.** Composite photo. (A) Right eye, (B) left eye.

Typical history of prodromal symptoms, lymphadenopathy, and cat exposure help strengthen the diagnosis, especially when presenting young adults or children.<sup>7</sup> Serological evaluation for anti-*Bartonella henselae* antibodies can aid in the diagnosis with sensitivity and specificity of 62% and 100%, respectively.<sup>9</sup> Occasionally, *Bartonella* bacilli can be isolated from lymph node biopsy in areas of lymphadenopathy.<sup>10</sup>

## IMAGING

Optical coherence tomography (OCT) images can demonstrate hyperreflective inner retina layers in the areas of white retinal lesions with shadowing of the posterior layers and choroid. Intraretinal and subretinal fluid can be seen along with exudates in the area of macular star formation. Fluorescein angiogram can demonstrate hyperfluorescence and leakage of the optic nerve and of any retinal lesions.<sup>11</sup>

## DIFFERENTIAL DIAGNOSIS

Etiologies that must be differentiated include other causes of optic nerve head swelling such as optic neuritis and sarcoid papillitis. Also, infectious

etiologies such as syphilitic perineuritis and (rarely) toxoplasmosis can produce similar clinical appearance. Pseudotumor cerebri can mimic the less frequent appearance of bilateral CSD. However, optic nerve vessels typically demonstrate obscuring of the vessels at the disc margin in pseudotumor and not in neuroretinitis. Finally, diabetic retinopathy with macular star formation can appear similar.

## **PATHOLOGY**

In animal models, *Bartonella* organisms typically invade and colonize mature erythrocytes. However, endothelial cells are also a target for *Bartonella* organisms and appear to be the target host cells in humans. Endothelial invasion leads to a proinflammatory response and formation of vasoproliferative tumors.<sup>12</sup>

In animal models, gamma-interferon activated macrophages have been documented to aid in clearing of *B. henselae* and may explain the self-limited nature of the infection.<sup>13</sup>

## **TREATMENT**

CSD tends to be a self-limiting disease. Usually no treatment is recommended, but antibiotic treatment has led to dramatic clinical responses in immunocompromised patients.<sup>3</sup> However, a course of antibiotics should be initiated in patients with severe ocular or systemic complications. Doxycycline (100 mg twice daily) tends to be the mainstay of therapy. It has good intraocular and central nervous system (CNS) penetration. In patients 8–12 years of age, erythromycin (30–50 mg/kg/day divided four times a day) is recommended due to the risk of tooth decoloration. Gentamycin, azithromycin, and rifampicin have also been used for systemic CSD.<sup>1</sup> Azithromycin has been observed to cause rapid resolution of lymphadenopathy.<sup>14</sup> However, the distribution of azithromycin into the eye appears higher for conjunctival tissue but lower in intraocular fluids.

## **WHIPPLE'S DISEASE: TROPHYRYMA WHIPPLEI-ASSOCIATED UVEITIS**

### **EPIDEMIOLOGY AND PATHOGENESIS**

Whipple's disease is a rare multisystemic disease caused by *Tropheryma whippelii*, a Gram-positive *Actinobacteria*. *Actinobacteria* are found in soil and water. Similar to fungi, they are important for decomposing organic material that are then taken up by plants and other living material. The classic clinical syndrome of a migratory arthritis, diarrhea, and weight loss can be seen, but symptoms vary widely. The disease most commonly affects white men in the fourth to sixth decades with an occupational exposure to soil or animals, although it has been reported to occur at any age.<sup>15</sup>

Arthritis is typically the first symptom experienced. The arthritis is migratory, occurring in 80% of patients. Gastrointestinal symptoms occur in approximately 75% of cases, producing abdominal pain with diarrhea, steatorrhea, and intestinal malabsorption. Weight loss is also common, with pitting edema due to protein-losing enteropathy. However, when gastrointestinal symptoms are not present, diagnosis can be difficult and can often be delayed for several years. Cardiac involvement can result in secondary heart failure or valvular regurgitation. Progression can lead to more serious CNS involvement producing dementia, coma, and seizures. Cranial nerves can also be involved, producing ophthalmoplegia and nystagmus.<sup>15</sup> Low-grade fever is present in 50% of cases. If left untreated, Whipple's disease can be ultimately fatal.

### **OCULAR MANIFESTATIONS**

Ocular involvement is estimated to occur in less than 5% of patients with Whipple's disease.<sup>16</sup> In most reported cases of Whipple's disease, ocular involvement typically is secondary to CNS involvement. These include nystagmus, oculomasticatory myorhythmia, and a progressive supranuclear-like palsy.

Inflammation can be bilateral with panuveitis and retinal vasculitis. Typically, both anterior uveitis and moderate vitritis are present. Rarely, unique white granular crystalline deposits can be seen at the pupillary margin and in the cornea.<sup>17</sup> Diffuse chorioretinal inflammation has also been observed. Diffuse vasculitis, typically in the perifoveal and midperipheral areas, are accompanied by hemorrhages and retinal vascular occlusions.<sup>18</sup> Optic nerve involvement can occur with prolonged involvement

leading to optic atrophy. A birdshot-like pattern of inflammation can also be seen.

## **DIAGNOSIS**

Diagnosis of Whipple's disease can be difficult in the absence of systemic signs. Duodenal biopsy remains the gold standard for diagnosis of Whipple's disease. The presence of strongly positive periodic acid-Schiff (PAS) bacillus within macrophages is virtually pathognomonic for the disease.<sup>16</sup> However, polymerase chain reaction (PCR) analysis of peripheral blood or vitreous samples has increasingly become an accurate and rapid form of identification.<sup>19</sup> Early diagnosis through PCR analysis of a vitreous biopsy may prevent the progression to more serious CNS involvement.

## **DIFFERENTIAL DIAGNOSIS**

Differential diagnosis includes entities that have multisystemic involvement and retinal vasculitis. These include systemic lupus erythematosus (SLE), polyarteritis nodosa (PAN), and Behçet's disease. Unlike Whipple's disease, SLE rarely produces intestinal malabsorption. Similarly, SLE and PAN tend to present with more vasculitic signs, with gastrointestinal hemorrhages or ischemia. Oral and genital ulcers seen in patients with Behçet's disease differentiate patients from Whipple's disease. Sarcoidosis can present with retinal vasculitis and ocular inflammation, but severe gastrointestinal findings are less frequently seen. In immunocompromised patients, mycobacterium avium intracellulare (MAI) can produce a similar systemic symptoms and histological picture (PAS positive). However, MAI tends to produce a multifocal choroiditis rather than a primary vasculitis.

## **PATHOLOGY**

*Tropheryma whippelii* has been difficult to culture, and no animal models of the infection currently exist. However, PAS-positive rod-shaped bacilli have been identified within macrophages and outside of cells in intestinal villi specimens.

## **TREATMENT**

Whipple's disease is a chronic recrudescence disease that can be fatal. Intestinal symptoms typically resolve within 1–3 months with treatment. However, relapses can occur in up to one-third of patients, requiring prolonged treatment for up to one year.<sup>20</sup> With ocular involvement, drugs that cross the blood-brain barrier are preferred. Double strength trimethoprim-sulfamethoxazole or doxycycline (100 mg twice daily) are the preferred first-line therapy. In sulfonamide-allergic patients, ceftriaxone or chloramphenicol can be tried. Retinal vasculitis typically responds to antibiotic treatment.<sup>18</sup> However, antibiotic treatment seldom resolves neurological signs, as they frequently become permanent. Doxycycline is typically combined with hydroxychloroquine (600 mg/day for 12 months) in patients with severe neurological symptoms, with doxycycline continued for life.

Infectious Endophthalmitis

Damien C. Rodger, Yevgeniy (Eugene) Shildkrot, Dean Elliott

7.9

**Definition:** Endophthalmitis is caused by infiltration of intraocular structures by an infectious agent, with associated inflammatory reaction involving the anterior and/or posterior segments of the eye.

Key Features

- Decreased vision.
- Pain.
- Conjunctival hyperemia.
- Intraocular inflammation, usually with hypopyon.

Associated Features

- Recent surgery.
- Trauma.
- Immunosuppression.
- Diabetes.
- Systemic infection.
- Indwelling catheters.
- Intravenous drug use.

INTRODUCTION

Infectious endophthalmitis is a potentially devastating condition involving the internal structures of the eye. It is one of the most feared complications of cataract extraction and other intraocular surgeries. Rarely, it can occur endogenously from a systemic nidus of infection.

EPIDEMIOLOGY AND RISK FACTORS

The pathogenic agents involved in endophthalmitis as well as the sources of infection are myriad. The following section and Table 79.1 summarize the common etiological associations and mimicking conditions.

TABLE 79.1 Categories of Endophthalmitis With Corresponding Mimicking Conditions

Type of Endophthamitis	Association	Mimicking Conditions
• Exogenous	• Penetrating surgery (cataract extraction, penetrating keratoplasty, glaucoma filtration surgery, vitreoretinal procedures)	• Toxic anterior segment syndrome
		• Postoperative inflammation
		• Retained lens material
• Endogenous	• Intravitreal injections	• Transient inflammation
	• Ocular trauma	• Chalcosis (occult intraocular foreign body)
	• Bacteremia (intravenous drug use, septicemia, endocarditis, liver abscess, indwelling catheters)	• Intraocular lymphoma
	• Fungemia	• Diffuse retinoblastoma (children)
	• Parasites	• Uveitis (panuveitis, intermediate, or posterior uveitis)
		• Medication-induced inflammation (e.g., rifabutin)

Endophthalmitis is classified on the basis of the source of the infection, as *exogenous*, which is the most common subtype, or *endogenous*. The avascular densely packed collagenous matrix of the cornea and sclera serves as a potent barrier against infectious infiltration in normal eyes. Violation of these structures, typically by surgery or trauma, makes the eye susceptible to the entry of pathogenic organisms and may lead to exogenous endophthalmitis. Bacteria are often the causative agents in these cases. There are typically no associated systemic findings, such as fever and minimal, if any, peripheral leukocytosis.<sup>1</sup>

Endogenous endophthalmitis occurs in otherwise stable eyes in association with transient or persistent bacteremia or fungemia. It is observed most frequently in immunosuppressed patients and intravenous drug users and less commonly in patients with cardiac valvular disease and persistent sites of infection elsewhere in the body and in those undergoing dental work. Fungal infections are most common, but a third of patients will present with bacterial endophthalmitis, often caused by Gram-negative species.<sup>2,3</sup>

Diabetes is the most frequent comorbidity in patients presenting with endophthalmitis of various causes and may be associated with an increased incidence of Gram-negative<sup>4</sup> and Gram-positive coagulase negative organisms.<sup>5</sup> Diabetes appears to increase the risk and possibly even the severity of endophthalmitis in patients undergoing glaucoma filtration procedures, vitrectomy, and cataract surgery and in patients with systemic *Klebsiella* infection.<sup>4,6–8</sup>

Exogenous Endophthalmitis

Trauma

The risk of endophthalmitis after open globe injuries (defined as a full-thickness defect of the cornea and/or sclera) in the Western world ranges from 4.2% to 7%.<sup>9–12</sup> In contrast, endophthalmitis is exceedingly rare after closed-globe injuries. Staphylococcal species are the most common causative agents in trauma-related endophthalmitis, and some species, such as *Bacillus cereus*, are seen almost exclusively in the context of trauma.<sup>13</sup> The source of the infection is typically the penetrating material, although the infection may rarely extend from contiguous sinuses in cases with orbital wall fracture. The rate of infection rises dramatically to 10%–15% when an intraocular foreign body is present and if the repair is delayed beyond 24 hours of the injury.<sup>9,11,12,14,15</sup> Even without overt infection, prophylactic intravitreal antibiotics should be considered at the time of the foreign body removal because in nearly a quarter of patients, cultures of the intraocular material will be positive for bacteria, and the risk of intravitreal antibiotics is generally low. In rural settings, where organic material contamination is common, endophthalmitis following penetrating ocular trauma reaches rates as high as 30%, with *Bacillus* species isolated in 46% of cases (Fig. 79.1) and polymicrobial isolates in 42%.<sup>16</sup> Of note, however, among patients within military combat zones, one study reported no cases of endophthalmitis after high-velocity projectile injury with intraocular foreign body despite delayed foreign body removal,<sup>17</sup> possibly a result of autosterilization from thermal heating<sup>18</sup>

Cataract Surgery

Postcataract endophthalmitis is categorized on the basis of the time to onset after surgery, as acute (within 6 weeks) or delayed. The incidence of endophthalmitis after cataract extraction is reported to be 0.04%–0.15%.<sup>19–23</sup> Some authors suggest an increase in the incidence of endophthalmitis beginning in the late 1990s/2000, in parallel with the increased use of clear corneal cataract wound placement.<sup>23,24</sup> Analysis of the large Medicare cataract databases, however, does not show a significant increase in the rate of endophthalmitis during 1994–2001 (0.2%) and 2003–2004 (0.1%).<sup>19,24</sup>

**Fig. 7.9.1** Endophthalmitis with corneal ring abscess caused by *Bacillus cereus* after penetrating trauma with a metal object.

Postcataract endophthalmitis is typically associated with defects in the surgical wound and violation of the posterior lens capsule, which can provide a route of entry for the infectious agents.<sup>25</sup> The patient's own periocular flora is the source of infection in the majority of cases of endophthalmitis. In 68%–82% of postcataract endophthalmitis cases, an identical genetic or molecular signature was present in the vitreous isolates and the commensal bacteria occupying the patient's conjunctiva, eyelids, or nose.<sup>26,27</sup> The Endophthalmitis Vitrectomy Study (EVS) was a major prospective randomized clinical trial analyzing the treatment of acute postoperative endophthalmitis, and it identified coagulase negative *Staphylococcus* in 70% of cases<sup>28</sup>; less common were *Staphylococcus aureus* in nearly 10%, *Streptococcus* species in 9%, *Enterococcus* in 2%, and Gram-negative organisms in 6%.<sup>28</sup>

In delayed-onset endophthalmitis, *Propionibacterium acnes* is the most commonly implicated pathogen, accounting for nearly 40% of isolates.<sup>29,30</sup> It has a subtle presentation and indolent course.

In pediatric patients undergoing intraocular surgery, the risk of endophthalmitis is estimated to be 0.07%–0.16%, with 82% of cases presenting by postoperative day 3.<sup>31,32</sup> Pediatric endophthalmitis is typically caused by Gram-positive bacteria; 47% of cases are associated with nasolacrimal duct obstruction or upper airway infection.<sup>31</sup>

Among the various antiseptics studied, 5% povidone iodine solution was the only perioperative intervention that was able to reduce the incidence of endophthalmitis.<sup>33</sup> A major randomized prospective trial conducted by the European Society of Cataract and Refractive Surgeons (ESCRS) suggested a benefit of using intracameral cefuroxime for reducing postcataract surgery endophthalmitis.<sup>34</sup> However, the results are controversial because the observed endophthalmitis incidence of 0.35% is significantly higher than previously described.<sup>34</sup> In addition, many surgeons routinely use intracameral vancomycin at the end of cataract surgery; however, this has been recently associated with hemorrhagic occlusive retinal vasculitis, a rare but devastating disease.<sup>35</sup> Short-term use of preoperative antibiotics may be beneficial, especially in patients with significant blepharitis and ocular surface disease.

### Penetrating Corneal Surgery

Corneal transplantation with penetrating keratoplasty appears to have a relatively high risk of infection compared with most other intraocular procedures. This probably results from the large circumferential incision and the use of donor tissue. Endophthalmitis occurs in 0.2%–0.4% of cases with a decline in incidence over the past decade.<sup>36</sup> The incidence of endophthalmitis following the implantation of a permanent keratoprosthesis

**Fig. 7.9.2** Endophthalmitis After Glaucoma Filtration Surgery. Note the white bleb filled with purulent material (arrow), conjunctival injection, corneal edema, and a hypopyon.

is higher, ranging from 5.4% to 7%, unless long-term postoperative topical vancomycin drops are used.<sup>37,38</sup> The causative agents following both the penetrating keratoplasty and keratoprosthesis surgeries are predominantly Gram-positive cocci, including *Streptococcus* and *Staphylococcus*, but Gram-negative organisms account for nearly 20% of cases.<sup>38,39</sup>

The overall frequency of endophthalmitis in corneal surgery is expected to decrease significantly with expanding indications for partial corneal transplantation utilizing smaller incisions, including Descemet's membrane stripping endothelial keratoplasty.

### Glaucoma Filtration Procedures

Glaucoma filtration surgery is associated with endophthalmitis in 2.1%–2.6% of cases.<sup>40,41</sup> Endophthalmitis following these procedures, unlike postcataract infections, tends to be delayed and is often associated with prior episodes of blebitis (Fig. 7.9.2).<sup>7</sup> Diabetes; use of antimetabolites, such as 5-fluorouracil and mitomycin; and inferior bleb location all increase the risk and hasten the onset of endophthalmitis.<sup>7,40–42</sup> The risk of endophthalmitis appears lower with fornix-based flaps. Delayed onset bleb-related endophthalmitis is associated most commonly with *Streptococcus* species (25%) and Gram-negative organisms, particularly *Haemophilus influenzae* (18%).<sup>41,43</sup>

### Vitrectomy

With the increasing shift to small-gauge sutureless surgery, there has been a concern regarding the increased incidence of postvitrectomy endophthalmitis. Although initial reports demonstrated an increased risk in patients undergoing 25-gauge surgery,<sup>44,45</sup> subsequent studies failed to confirm these findings, probably because of the increased use of conjunctival displacement, biplanar shelved incisions for cannula placement, and judicious use of sutures, when necessary. Recent studies estimate the incidence of endophthalmitis as 0.02%–0.04% in 20-gauge, 0.03% in 23-gauge, and 0.01%–0.02% in 25-gauge vitrectomies.<sup>44,46,47</sup> In addition, the use of tamponade agents, such as gas or oil, may further lower the risk.<sup>48</sup> *Staphylococcus* species account for more than 50% of cases.<sup>49</sup>

### Intravitreal Injections

Intravitreal injections of triamcinolone for various causes, although they can cause a sterile inflammatory response easily confused for infectious endophthalmitis, also have a 0.87% incidence of infectious endophthalmitis,<sup>50</sup> possibly as a result of inhibition of immune function against inadvertently introduced pathogenic agents.<sup>51</sup> Accordingly, the intravitreal injections of anti-vascular endothelial growth factor medications, including ranibizumab, are associated with significantly lower endophthalmitis rates of 0.02%–0.08%.<sup>52–54</sup> Patients with diabetes may, however, be at higher risk. Most of the cases are caused by *Streptococcus* or *Staphylococcus* species representing the commensal flora of ocular adnexa and oropharynx.<sup>53,54</sup>

**Fig. 7.9.3 Gross Specimen of Coagulation Necrosis With Extensive Tissue Destruction.** Note the optic (translucent arrow) and the haptic (black arrow) of an intraocular lens.

The risk of infection may be lessened by decreasing the oropharyngeal droplet transmission at the time of the injection.<sup>55</sup>

Parceling single medications, such as bevacizumab, into multiple intravitreal injections by compounding pharmacies can theoretically increase the incidence of infection and has been associated with local outbreaks of endophthalmitis.<sup>56</sup> Recent data have shown, however, that endophthalmitis rates with bevacizumab, ranibizumab, and aflibercept intravitreal injections are statistically no different.<sup>57</sup> The use of postinjection antibiotics does not appear to decrease the frequency of subsequent endophthalmitis but, in fact, may lead to selection of drug-resistant bacteria in the nasopharynx and on the ocular surface.<sup>58</sup>

### Endogenous Endophthalmitis

Hematogenous spread of a bacterial infection is often seen in patients with transient or persistent bacteremia from various causes. Endogenous endophthalmitis is caused more commonly by Gram-positive organisms in the Western world, while Gram-negative organisms account for as many as 70% of isolates from eyes with endogenous endophthalmitis in Asian countries.<sup>59,60</sup> A common Gram-negative pathogen is the K1 subtype of *Klebsiella pneumoniae*, which is associated with concurrent hepatobiliary infections in 48%–77% of cases.<sup>8,59,61,62</sup> Fungal dissemination of *Candida albicans*, *Aspergillus* species, and other fungi may also lead to endogenous endophthalmitis, usually in patients with concomitant fungemia, underlining the importance of dilated funduscopic examinations in patients with positive fungal blood culture results.

## PATHOLOGY AND PATHOGENESIS

The clinical course of endophthalmitis is associated with intravitreal elaboration of inflammatory cytokines, including tumor necrosis factor- $\alpha$ , interleukin-1 $\beta$ , and interferon- $\gamma$ .<sup>63</sup> This results in neutrophil aggregation leading to suppurative or nonsuppurative inflammation and a variable degree of tissue necrosis (Fig. 7.9.3). Fas ligand, which functions in retinal apoptotic pathways, appears critical in preventing *S. aureus* endophthalmitis following experimental inoculation, and the complement pathway does not appear to have an important role.<sup>64</sup>

## CLINICAL PRESENTATION AND EVALUATION

Acute endophthalmitis is an ophthalmological emergency requiring a high degree of suspicion leading to prompt recognition, diagnosis, and therapy. A thorough history should be obtained, with particular emphasis on identifying possible causes of immunosuppression, a history of trauma, and medication allergy status. An indolent course and impaired immune function can lead to severe infections that can be easily misdiagnosed as uveitis. The examination of the anterior segment should include a Seidel test for occult leakage of a wound (Fig. 7.9.4A–C), evaluation for the presence of a vitreous wick to the wound (Fig. 7.9.5) or the presence of a white plaque on the intraocular lens or capsule. The view of the posterior segment is often limited, and ultrasonographic evaluation may be necessary to document the baseline presence of tractional membranes or retinal detachment. The morphological features of any infectious nidus or abscess can also aid in diagnosis, as fungal lesions often project from the retina into the vitreous

cavity in a mushroom-like configuration (Fig. 7.9.6A, B), whereas bacterial abscesses, such as those caused by *Klebsiella*, may appear subretinally (see Fig. 7.9.6C). Unless a clear etiology is present, a systemic evaluation for sources of infection may be prudent, including blood cultures, chest radiography, liver ultrasonography, and cardiac ultrasonography, to look for valvular vegetations or a patent foramen ovale.

The presenting symptoms and signs of endophthalmitis are variable. In the EVS, 98% of patients with acute endophthalmitis presented with  $\geq 1$  of the four classic symptoms, including decreased vision (93%), conjunctival injection (81%), pain (75%), and lid swelling (33%) (Fig. 7.9.7A).<sup>65</sup> These findings are not universal, however, as pain and hypopyon were found to be absent in one quarter of patients with acute endophthalmitis.<sup>65</sup> Hypopyon can sometimes be very small (see Fig. 7.9.7B). In patients with delayed endophthalmitis, the presenting features are even more variable and often subtle. *Propionibacterium acnes* endophthalmitis can present with mild iritis, pigmented keratic precipitates in the absence of severe pain, or visual decline.<sup>66</sup> Hypopyon is seen in fewer than half of cases of delayed endophthalmitis.<sup>30</sup> The symptoms may be precipitated or exacerbated by laser capsulotomy. On examination, the most common findings are vitritis, a white plaque on the posterior capsule or the intraocular lens (Fig. 7.9.8), beaded fibrin strands, hypopyon, granulomatous-appearing keratic precipitates, and cystoid macular edema.<sup>30,66</sup>

## MICROBIOLOGICAL TESTING

Gram stain and culture are central to determining the ultimate diagnosis and are a critical step in the management; however, they rarely influence the choice of antibiotics and should be obtained typically concomitantly with initial presumptive treatment. The cultures should include aerobic, anaerobic, and fungal media. The diagnostic material is usually obtained in the office by aqueous paracentesis and vitreous aspirate or in the operating room via pars plana vitrectomy. Portable vitrectomy machines enable in-office emergent vitrectomy, although this is rarely performed. The EVS did not demonstrate any difference in the microbiological yield between needle vitreous aspiration and mechanized vitreous biopsy, with successful identification of the causative organism in 41%–42% on initial Gram stain and 66%–69% on culture.<sup>67,68</sup> Culture of both the undiluted vitreous biopsy specimen and the vitreous cassette can further increase the yield after vitrectomy.<sup>68,69</sup>

When *P. acnes* is suspected as the causative agent, the microbiology laboratory should be instructed to incubate the culture for at least 14 days because of the slow growth rate.<sup>66</sup>

Newer techniques, such as DNA microanalysis and polymerase chain reaction (PCR) testing, can increase the diagnostic yield by 20% and provide rapid results, often within 24 hours, with only small amounts of vitreous being required.<sup>70,71</sup> This is of particular benefit in suspected fungal infections, where it often takes many days for fungal cultures to result positively.

## DIFFERENTIAL DIAGNOSIS

See Table 79.1 for the mimicking conditions that should be considered in the workup of endophthalmitis in various clinical scenarios.

**Fig. 7.9.4** Endophthalmitis following cataract surgery with incomplete wound closure (A) and wound leakage on Seidel testing (B–C).

## TREATMENT

The treatment of endophthalmitis is dependent on the etiology of the inciting agent. The treatment may include intravitreal antibiotics, surgery, and/or systemic therapy. The algorithm for the management of acute postcataract endophthalmitis is dictated to some extent by the findings of the EVS (see below).

### Medications

Various agents may be considered for intravitreal injection (Box 7.9.1). The most commonly used medications in suspected bacterial endophthalmitis include vancomycin and ceftazidime. Intravitreal vancomycin provides broad coverage for over 99% of Gram-positive organisms, and ceftazidime is effective against 100% of Gram-negative bacteria observed in

**Fig. 7.9.5** Vitreous wick (arrow) extending to the corneal paracentesis.

postoperative endophthalmitis.<sup>72</sup> Second-line agents can be considered in patients with documented medication allergies, although their efficacy and potential for complications should be balanced against the severity of the stated allergy to a first-line medication. Intravitreal gentamycin should be avoided because of the well-known association with macular infarction. Other aminoglycosides, including amikacin and tobramycin, also have a well-documented potential for macular toxicity.<sup>73</sup> Furthermore, in recent years, there has been increasing frequency of resistance to the medications used for the prophylaxis of endophthalmitis, leading to reduced efficacy for the treatment of the infection. Resistance to ciprofloxacin and ceftazolin was observed in nearly 40% of the bacterial isolates from eyes with postcataract endophthalmitis.<sup>72</sup> Gram-negative bacteria, particularly *Pseudomonas*, although fortunately rare as a cause of endophthalmitis, can demonstrate multidrug resistance in up to 78.6% of the isolates in some series.<sup>74</sup> Periocular and subconjunctival antibiotics do not appear to have sufficient vitreous penetration nor significant clinical benefit to warrant routine use.<sup>75,76</sup>

Intravitreal corticosteroids, coadministered with antibiotics, may ameliorate the immune-driven destruction of ocular tissues and improve outcomes in eyes with endophthalmitis caused by *S. aureus*, *S. epidermidis*, and *B. cereus*.<sup>77–79</sup> Intravitreal dexamethasone may also be beneficial in cases of delayed bleb-associated endophthalmitis.<sup>80</sup> However, treatment of endophthalmitis with corticosteroids remains controversial.

The EVS did not demonstrate a benefit of adjunctive systemically administered medications optimized for Gram-negative coverage.<sup>81</sup> However, because Gram-positive organisms are implicated in the majority of postoperative endophthalmitis cases, systemic treatment with appropriate medications may be warranted, particularly in severe cases. Fluoroquinolones, including levofloxacin and gatifloxacin, even when administered orally, are able to achieve therapeutic intravitreal levels for the most important pathogenic agents, albeit not for *Pseudomonas aeruginosa* or *Enterococcus*.<sup>82,83</sup> Mycotic endophthalmitis is usually treated with systemic antifungal agents with good vitreous penetration, such as fluconazole, voriconazole, ketoconazole, or amphotericin B, and intravitreal voriconazole or amphotericin B.<sup>84</sup>

### Surgical Intervention

The results of the EVS are still applicable to postcataract endophthalmitis cases today, with some modifications. In patients presenting after cataract surgery with intraocular inflammation and visual acuity at the level of light perception, compared with intravitreal antibiotics alone, pars plana vitrectomy with injection of intravitreal antibiotics appeared to improve the visual outcomes. For patients with visual acuity of hand motion or better, vitrectomy with intravitreal antibiotics appeared to provide no additional visual benefit when compared with intravitreal antibiotics alone. Subanalysis, however, suggested that among patients with diabetes and better

**Fig. 7.9.6** B-scan ultrasonography images depicting the mushroom-like configuration of *Candida* (A) and *Aspergillus* (B) endogenous lesions compared with the subretinal abscess of *Klebsiella* (C).

**Fig. 7.9.7** Acute postcataract endophthalmitis can vary in presentation depending on the causative agent from a fulminant picture with corneal edema and a large hypopyon (A) to a more moderate form with a subtle hypopyon (arrow) (B).

**Fig. 7.9.8** Acute focal posterior capsular plaque (arrow) seen in a patient with *Propionibacterium acnes* endophthalmitis.

#### BOX 7.9.1 Intravitreal Agents Used in the Treatment of Endophthalmitis

Alternatives	Amikacin Cefazolin Cefuroxime Clindamycin Amphotericin B

presenting vision, more will achieve 20/40 or better ultimate vision if vitrectomy is performed.<sup>6</sup>

The main goals of pars plana vitrectomy in endophthalmitis are to obtain sufficient tissue for diagnosis and to debulk the proinflammatory debris. In practice, a culture result of the removed material alters clinical management in <5% of cases. Although the EVS included limited vitrectomy, more extensive debridement may provide better outcomes. In addition, early surgical intervention may be of particular benefit in fungal endophthalmitis, where retinal detachment rates for *Candida* infections were found to be far lower when vitrectomy was performed within 1 week of presentation compared with delayed vitrectomy. Removal of the intraocular lens implant is typically not required, except in cases of chronic low-grade endophthalmitis associated with *P. acnes* resistant to medical therapy.<sup>30,85</sup>

## OUTCOMES

In general, the outcomes for endophthalmitis are poor despite aggressive therapy and the frequent need for subsequent surgical procedures. The virulence of the infectious agent dictates the course and outcome of the infection. Less aggressive organisms elicit milder intraocular inflammation and are associated with longer delay from inoculation to clinical manifestations. Consequently, media opacity mild enough to allow visualization of retinal vessels at the time of the diagnosis purports better outcomes.<sup>5,59</sup> Visual outcomes are worse with endophthalmitis developing within 2 days of surgery, presenting vision of light perception or worse, the presence of an afferent pupillary defect, and in patients with diabetes.<sup>4-8</sup> Outcomes in children with exogenous endophthalmitis are particularly poor, with >60% having worse than 20/400 vision, even with aggressive therapy involving vitrectomy and intravitreal antibiotics.<sup>31,86</sup>

Best visual outcomes are observed in patients with *P. acnes* species, where 91% of patients achieve at least 20/100 vision.<sup>30</sup> In the EVS, this level of vision was achieved in 84% of eyes with Gram-positive coagulase-negative infections, but in only 50% of *S. aureus* infections and 56% of Gram-negative infections.<sup>87</sup> *Pseudomonas*, *Klebsiella*, *S. pneumoniae*, and *Bacillus* species are associated with a particularly aggressive course and severe vision loss. *P. aeruginosa* endophthalmitis is associated with nearly universal vision loss beyond 20/400 and the ultimate need for enucleation in 64%.<sup>88</sup> *Klebsiella* endophthalmitis leads to no light perception vision in 58%–89% and enucleation in 21%–41%.<sup>8,89</sup> *S. pneumoniae* endophthalmitis has a slightly better, although still poor, outcome, with 30% of patients achieving vision of 20/100 or better, and 37% with no light perception.<sup>86,90</sup> Endophthalmitis involving *Bacillus* species is associated with 20/400 or better vision in 36%, with nearly half of those eyes achieving vision of 20/60 or better, whereas enucleation is necessary in only 5%.<sup>13</sup> Endogenous mycotic infections have a generally poor prognosis, and of these, *Aspergillus* species infections have significantly worse outcomes than those of *Candida* species.<sup>91</sup>

Endophthalmitis following penetrating globe injuries is associated with very poor visual outcomes, including no light perception vision or enucleation in 82.3%.<sup>9</sup>

Additional surgical intervention may be required in more than a third of patients with postoperative endophthalmitis, often with poor ultimate outcome.<sup>92</sup> In the EVS, retinal detachment was observed in 8.3% of patients after either vitreous tap/inject or vitrectomy.<sup>93</sup>

## CONCLUSIONS

The devastation caused by infectious bacterial endophthalmitis can be vision and eye threatening. Patients with a history of diabetes, trauma, or

surgery are at a particularly high risk for developing endophthalmitis. The typical signs, including pain and hypopyon, are not universally present, so a high index of suspicion is warranted to prevent delay in diagnosis.

# Histoplasmosis

Mark M. Kaehr, Ramana S. Moorthy

# 7.10

**Definition:** Ocular histoplasmosis is an intraocular inflammation induced by *Histoplasma capsulatum*, a diphasic fungus.

## Key Features

Three characteristic presentations:

- Endophthalmitis.
- Solitary granuloma.
- Syndrome characterized by peripheral “punched-out” chorioretinal scars, absence of inflammatory cells in the anterior chamber or vitreous, and positive histoplasmin skin test results (most common).

## Associated Features

- Peripapillary chorioretinal atrophy.
- Choroidal neovascularization.
- Peripheral punched-out lesions.
- Linear chorioretinal scars (“linear streaks”).
- Endemic in the Ohio River and Mississippi River valleys in the United States.

## INTRODUCTION

*Histoplasma capsulatum* is a diphasic, soil-borne fungus. Humans and other mammals inhale wind-blown soils and aerosolized bird droppings that contain these organisms and so become infected. These organisms infect the lungs and can be disseminated through the systemic circulation to other organs such as the liver, kidney, spleen, and the eye. *H. capsulatum* is responsible for three different forms of ocular involvement in humans:

- Endophthalmitis with diffuse uveal and retinal involvement from disseminated histoplasmosis.
- Solitary chorioretinal granuloma.
- Ocular histoplasmosis syndrome (OHS).

The *Histoplasma* organisms have been identified in ocular tissues in all three of these forms.<sup>1</sup>

Histoplasmic endophthalmitis occurs mainly in immunocompromised patients, particularly those who have acquired immune deficiency syndrome (AIDS). Symptoms can include floaters, decreased vision, and pain in the affected eye. Ophthalmic examination reveals conjunctival injection, anterior chamber flare and cells, yellow iris infiltrates, posterior synechiae, vitreous cells, and multiple white, creamy foci of retinochoroiditis.<sup>1,2</sup> Diagnosis is based on the presence of active pulmonary or disseminated histoplasmosis and positive cultures from sputum, bronchial washings, and biopsy specimens from the anterior chamber or vitreous cavity. Complement fixation titers are elevated (>1:32) in disseminated disease. Histopathological evaluation of eyes with histoplasmic endophthalmitis demonstrates diffuse granulomatous inflammation that involves the entire uveal tract, focal retinal inflammation, and intracellular and extracellular *H. capsulatum* that are detected with periodic acid-Schiff and Gomori’s methenamine-silver (GMS) stains.<sup>1,2</sup> Prompt treatment with systemic amphotericin B or itraconazole is recommended in affected patients.

Solitary histoplasmic granuloma is an extremely rare condition found in immunocompromised patients,<sup>1</sup> often in the absence of an identifiable primary source infection, characterized by a unilateral, ill-defined choroidal lesion.<sup>1</sup> Vitritis is variable. Histopathological evaluation shows a dense, granulomatous mass containing lymphocytes, epithelioid and giant cells,

and few *Histoplasma* organisms.<sup>1</sup> Treatment with systemic amphotericin B should be considered if a granuloma appears to be growing or is associated with severe vitritis.

OHS is by far the most common form of ocular disease caused by *H. capsulatum*. It continues to be an important cause of central visual loss during the productive years of human life. The syndrome consists of:

- Peripapillary chorioretinal atrophy and scarring.
- Peripheral punched-out chorioretinal scars.
- Hemorrhagic macular lesions secondary to choroidal neovascularization (CNV).
- Absence of anterior segment and vitreous inflammation.
- A positive histoplasmin skin test result.<sup>3</sup>

## EPIDEMIOLOGY AND PATHOGENESIS

OHS is endemic in the Ohio and Mississippi River valleys of the eastern half of the United States. Up to 80 million people are at risk of developing OHS in this part of the country.<sup>4</sup> *H. capsulatum* may cause a subclinical systemic infection in patients in the endemic areas prior to the development of the typical ocular manifestations of OHS. This may be a self-limited upper respiratory tract illness. Subsequent routine radiological studies of patients in endemic areas may disclose asymptomatic pulmonary, hepatic, splenic, and renal granulomas. In endemic areas, 60% or more of the population may have positive histoplasmin skin tests, and 5% of these people have peripheral atrophic scars and peripapillary atrophy. Additionally, 95% or more of patients who have typical signs of OHS have positive histoplasmin skin test results.<sup>5</sup> Although *H. capsulatum* has not been cultured from chorioretinal or disciform scars, organisms have been demonstrated histopathologically in both,<sup>6</sup> and fragments of the DNA of *H. capsulatum* have been detected by polymerase chain reaction (PCR) in atrophic scars.<sup>7</sup> These observations suggest that *H. capsulatum* causes OHS.

Genetic factors may be important in the pathogenesis of OHS, because patients with macular or peripapillary hemorrhagic lesions have a significantly higher prevalence of human lymphocyte antigen B-7 (HLA-B7) than the general population or those who have only peripheral atrophic spots associated with OHS.<sup>8</sup> Smoking increases threefold the risk of the development of CNV in patients with OHS.<sup>9</sup> Conversely, there is evidence that many of the genes that confer increased risk of CNV for AMD do not increase risk of CNV in OHS.<sup>10</sup>

## OCULAR MANIFESTATIONS

Ocular manifestations of histoplasmosis classically are confined to chorioretinal pathology. However, there have been case reports of scleritis and ocular adnexal involvement.<sup>11,12</sup>

With intraocular disease, anterior segment and vitreous inflammation are notably absent. The characteristic fundus findings of OHS include:

- Small oval to round, punched-out, chorioretinal scars in the midperiphery or posterior pole (Fig. 7.10.1A).
- A macular lesion that varies from atrophic scar to active choroidal neovascularization (see Fig. 7.10.1A) to disciform scar.
- Peripapillary atrophy or scarring (see Fig. 7.10.1A).

The peripheral chorioretinal lesions are discrete, punched-out, atrophic scars that are 0.2–0.6 disc diameters in size. They often have pigmented borders and may be located in the midperiphery or in the posterior pole. The macular lesions may begin as atrophic scars. A CNV can arise from the scar and can be associated with a pigment ring, overlying subretinal fluid, and/or hemorrhage. If untreated, these lesions may evolve into disciform scars. The disciform lesion may appear yellowish to whitish, fibrotic,

**Fig. 7.10.1** (A) Peripheral punched-out scars, macular lesion, and peripapillary atrophy with pigmented ring in the left eye of a patient with ocular histoplasmosis syndrome. (B) New lesions demonstrating a subclinical inflammatory component. Same patient as in Fig. 7.10.1A 10 years later with new lesions on clinical examination. (C) Fundus autofluorescence showing more lesions than clinically evident. Arrows show foci of retinal pigment epithelial disruption and scarring that cannot be seen on biomicroscopy.

**Fig. 7.10.2 Choroidal Neovascularization in OHS.** (A) Autofluorescence image of the right eye of a patient with new metamorphopsia shows a hyperautofluorescent juxtafoveal choroidal neovascular membrane (CNVM). (B) Fluorescein angiogram shows lacy hyperfluorescence consistent with classic CNVM. (C) Spectral domain optical coherence tomography shows the neovascular lesion and adjacent subretinal fluid.

and associated with variable amounts of pigmentation. The size of the disciform macular scar can vary depending upon the amount of serum and blood in the subretinal space prior to its development.<sup>7</sup> Peripapillary scarring is associated with a thin area of chorioretinal atrophy adjacent to the optic nerve and a peripheral zone of hyperpigmentation at the edge farthest from the optic nerve (see Fig. 7.10.1A). Choroidal neovascularization also may develop in the peripapillary area and result in peripapillary subretinal hemorrhage and serous retinal detachment, which may occasionally involve the macula. In addition to the three characteristic retinochoroidal lesions, linear streak lesions at the equator have been found in some patients with OHS. Equatorial linear streak lesions, however, also may be seen in idiopathic multifocal choroiditis.<sup>13</sup> Patients may also develop new lesions over time that are demonstrative of a subclinical, ongoing inflammatory component to the disease (see Fig. 7.10.1B).

Patients who have OHS generally are asymptomatic unless choroidal neovascularization causes metamorphopsia.<sup>14</sup> This usually is followed by visual loss and the development of a small scotoma in the central or para-central visual field. Patients who have OHS usually seek treatment for these symptoms between their third and sixth decades.<sup>14</sup>

## DIAGNOSIS

The diagnosis of OHS is made by funduscopic examination alone. Skin testing with *H. capsulatum* antigen is not recommended because of the high prevalence of positive results in endemic areas and controversy as to whether the skin test may actually cause activation of otherwise quiet, atrophic chorioretinal scars.<sup>15</sup>

Patients with known asymptomatic OHS should be instructed to perform frequent Amsler chart self-monitoring for early detection of choroidal neovascularization.<sup>14</sup> Fundus autofluorescence may also demonstrate small, clinically unapparent macular scars that may suggest the need for closer Amsler grid monitoring<sup>16</sup> (see Fig. 7.10.1C). Patients who have OHS who have symptoms of metamorphopsia or scotoma should have

### BOX 7.10.1 Differential Diagnosis of Ocular Histoplasmosis Syndrome

- Punctate inner choroiditis
- Sarcoid panuveitis
- Vogt–Koyanagi–Harada syndrome
- Sympathetic ophthalmia
- Idiopathic multifocal choroiditis
- Myopic degeneration

fluorescein angiography performed (see Fig. 7.10.2A). In asymptomatic patients, fluorescein angiographic findings consist of late staining of the peripapillary scar, midperipheral atrophic spots, and atrophic macular scars. If clinical examination suggests the presence of subretinal fluid or a subretinal hemorrhage, fluorescein angiography demonstrates early hyperfluorescence and late leakage from a complex of lacy, small blood vessels in the subretinal space or subretinal pigment epithelial space (Fig. 7.10.2B). This is consistent with the diagnosis of choroidal neovascularization. Similar findings are seen on indocyanine green angiography, which may be helpful in delineating the CNV when it is obscured by subretinal hemorrhage. Spectral domain optical coherence tomography (SD-OCT) can also be used to visualize and quantify subretinal fluid due to CNV and the response to treatment (see Fig. 7.10.2C). SD-OCT of “histo spots” and peripapillary atrophy demonstrates outer retinal loss and retinal pigment epithelial (RPE) atrophy, and the infrared image of peripapillary atrophy (PPA) shows a hyperreflective halo.<sup>16</sup>

## DIFFERENTIAL DIAGNOSIS

All of the syndromes listed in Box 7.10.1, except myopic degeneration and punctate inner choroiditis, have anterior segment and vitreous

**Fig. 7.10.3 Histopathology of an “Active” Atrophic Chorioretinal Scar in Ocular Histoplasmosis Syndrome.** Note the lymphocytic infiltrate of the choroid, disruption of Bruch’s membrane and retinal pigment epithelium, and extension of inflammation from choriocapillaris into the subretinal space. Typical Histoplasma organisms are not demonstrated here but have been isolated from other lesions. (Courtesy Yanoff M, Fine BS. Ocular pathology: a text and atlas. 4th ed. St Louis: Mosby; 1994. p. 395.)

inflammation in association with the chorioretinal findings. Peripheral, punched-out scars, atrophic and disciform macular scarring, and peripapillary atrophy, scarring, and choroidal neovascularization also may occur in all of these syndromes. Differentiating punctate inner choroiditis (PIC) and idiopathic multifocal choroiditis (MFC) from OHS is of particular importance in endemic areas because the management of the chronic, inflammatory component of PIC and MFC may be required, and the incidence of new CNV is much higher in PIC compared to OHS (see Chapter 7.22).

## PATHOLOGY

Histopathology of peripheral lesions demonstrates the infiltration of lymphocytes.<sup>17</sup> Caseating granulomatous foci with fibrohyaline scarring may be present.<sup>17</sup> The granulomas may contain *H. capsulatum*.<sup>6,7</sup>

The macular lesions of OHS show disruption of Bruch’s membrane with ingrowth of a neovascular complex into the subretinal space (Fig. 7.10.3).<sup>18</sup> There may be an overlying serous retinal detachment and subretinal hemorrhage. A variable amount of lymphocytic infiltration may be present. The CNV may appear only loosely adherent to the overlying photoreceptors and underlying native RPE.<sup>18</sup> If left untreated, the subretinal hemorrhage and serum in the subretinal space may lead to proliferation and metaplasia of RPE into fibrovascular tissue that organizes into an inactive disciform plaque.<sup>17</sup> Lymphocytes can sometimes become a prominent feature of the choroid adjacent to the subretinal scar.<sup>17</sup> The peripapillary scar also demonstrates RPE proliferation and replacement of much of the choroid by fibrovascular tissue.<sup>17</sup> Disruption of Bruch’s membrane and extensive destruction of the overlying photoreceptors also may occur in this area.<sup>19</sup>

Surgically excised CNVs demonstrate the expression of various growth factors—basic fibroblast growth factor, transforming growth factor  $\beta$ -1, and procollagen.<sup>20</sup> These growth factors play a role in the development of choroidal neovascularization.

## TREATMENT

Most patients who have OHS are asymptomatic unless they develop choroidal neovascularization in the peripapillary or macular regions. Macular choroidal neovascularization was traditionally subdivided into the following<sup>20</sup>:

- Extrafoveal lesions, when the foveal edge is more than 200  $\mu$ m from the center of the fovea.
- Juxtafoveal lesions, when the foveal edge is 1–199  $\mu$ m from the center of the fovea.
- Subfoveal lesions, when any part of the membrane has clearly grown underneath the center of the fovea.

This location classification system was important when laser photocoagulation with argon green<sup>21</sup> or krypton red<sup>22</sup> laser was the treatment of choice. Untreated eyes with CNV and ocular histoplasmosis have a

3–6 times greater risk of losing six or more lines of visual acuity than do treated eyes. Laser treatment, however, leaves a scotoma in the treated area and has recurrence rates of 26%.<sup>21,22</sup> Hence laser is rarely used today since the advent of anti-vascular endothelial growth factor (VEGF) therapy. Continued Amsler chart monitoring for new metamorphopsia is important.

Today laser treatment is rarely, if ever, used for juxtafoveal and subfoveal CNVs. Inhibition of VEGF, an important vasoproliferative cytokine, using monoclonal antibodies (bevacizumab, ranibizumab, and aflibercept) directed against VEGF and its receptor has shown to be a highly effective method of controlling many forms of ocular neovascularization. Intravitreal bevacizumab (IVB) is now the preferred treatment for juxtafoveal and subfoveal choroidal neovascular membranes in OHS.

Unlike thermal laser treatment for CNV, IVB therapy does not produce a scotoma.<sup>23</sup> The largest retrospective study to date, of 117 eyes with OHS and CNV,<sup>23</sup> demonstrated that 30% of patients gained three or more lines of vision, 80% maintained stable or better after 3 years of follow-up and after receiving an average of three IVB injections per year. In addition, after 3 years of follow-up, less than 10%<sup>23</sup> of eyes had visual acuity less than or equal to 20/200, compared with 75% by natural history.<sup>24</sup> Ocular complications such as endophthalmitis, vitreous hemorrhage, or retinal detachment need to be discussed with the patient before initiation of IVB therapy. Despite its widespread ocular use worldwide for 12 years, bevacizumab is not yet approved by the US Food and Drug Administration (FDA) for use in the eye. There are reports of the use of ranibizumab and aflibercept in OHS, but these medications may remain cost prohibitive in the absence of an FDA indication for CNV secondary to OHS.<sup>25,26</sup>

Ocular photodynamic therapy using verteporfin may also be utilized for subfoveal<sup>27</sup> and juxtafoveal<sup>28</sup> CNVs. The Verteporfin in Ocular Histoplasmosis (VOH) study, a multicenter, uncontrolled, prospective clinical trial for subfoveal CNV,<sup>27</sup> concluded that after 24 months and an average of 2.9 treatments, 45% (14/22 eyes) had improved seven or more Early Treatment of Diabetic Retinopathy Study (ETDRS) letters of visual acuity from baseline. There were no systemic or ocular adverse events reported.<sup>27</sup>

Subfoveal surgery to remove CNVs in ocular histoplasmosis requires pars plana vitrectomy, disinsertion, and removal of the posterior hyaloid, a small retinotomy, and careful delamination, dissection, and removal of the CNV from the subretinal space.<sup>29–31</sup> The Submacular Surgery Trials (SST) were multicenter, randomized, clinical trials designed to determine whether there was significant clinical and quality of life benefit in surgical removal of subfoveal choroidal neovascularization in various disorders, including OHS compared to observation alone. The 24-month data from 225 patients enrolled in this trial showed no treatment benefit for idiopathic or OHS-associated subfoveal choroidal neovascularization.<sup>32</sup> Risks of surgery including retinal detachment, cataract, and recurrence of subfoveal choroidal neovascularization (in more than 50% within 1 year)<sup>31</sup> preclude the need for subfoveal surgery since the advent of highly effective anti-VEGF therapy.

## COURSE AND OUTCOME

Patients with OHS but without macular complications of the disease enjoy excellent visual acuity and visual prognosis. Treatment of extrafoveal choroidal neovascularization with argon or krypton laser photocoagulation reduces the risk of serious visual loss by at least 50%.<sup>21</sup> Extrafoveal choroidal neovascularization has an excellent visual prognosis after treatment.<sup>21</sup> The visual prognosis for juxtafoveal and subfoveal choroidal neovascularization has improved substantially with PDT<sup>27</sup> and IVB.<sup>23</sup> In earlier studies, more than 75% of patients who have subfoveal choroidal neovascularization had visual acuity of 20/100 (6/30) or worse after 3 years.<sup>24</sup> Today, only about 10% of patients developed severe visual loss ( $\leq$ 20/200) after 3 years of IVB therapy.<sup>23</sup> However, natural history data demonstrates that up to 14% of eyes with subfoveal choroidal neovascularization may retain visual acuity of 20/40 (6/12) or better if the patient is less than 30 years of age, has small CNVs involving less than 50% of the foveal avascular zone, and has no visual loss secondary to OHS in the fellow eye.<sup>33</sup> Spontaneous visual acuity recovery has also been reported in younger patients with smaller central disciform scars and shorter intervals of sequential visual loss, particularly when visual acuity drops to 20/80 (6/24) or worse in the fellow eye.<sup>33</sup> Such visual acuity recovery also may occur from spontaneous involution of subfoveal choroidal neovascularization in some rare instances.

Patients with a disciform scar or choroidal neovascularization in one eye and evidence of macular atrophic scars in the high-risk region (defined vertically between the temporal arcades, nasally by the temporal disc margin, and temporally by disc to fovea distance from the foveal center) in the fellow eye have approximately a 20% risk over a 2- to 3-year period of

developing choroidal neovascularization in the macula of the fellow eye.<sup>24</sup> Patients who do not have macular lesions are at significantly lower risk of developing choroidal neovascularization. However, de novo choroidal neovascularization has been reported in patients with OHS who did not appear to have macular scars.

Reactivation of inflammatory lesions may also occur in patients with OHS.<sup>34</sup> This phenomenon dispels the notion of OHS being a static disease and may explain the development of new lesions and enlargement of old chorioretinal scars in patients with OHS. Patients with reactivation may complain of decreased vision and metamorphopsia. Reactivation usually is not accompanied by vitritis. Clinical examination may demonstrate mild graying of the choroid and/or RPE and thickening of the retina. Fluorescein angiography of reactivated lesions demonstrates progressive leakage with irregular borders without evidence of underlying CNV.<sup>34</sup> Patients may be treated with systemic itraconazole combined with oral corticosteroids, which also may be used alone.<sup>34</sup> Most lesions improve within 4–12 weeks. Choroidal neovascularization only rarely occurs after several months at the site of these reactivated lesions.<sup>34</sup>

# Fungal Endophthalmitis

Dimitra Skondra, Dean Elliott

# 7.11

**Definition:** Fungal endophthalmitis is an intraocular inflammation leading to various degrees of inflammation, either acute or chronic, induced by fungi such as *Candida albicans*, *Fusarium* species, *Coccidioides immitis*, and *Aspergillus* spp.

## Key Features

- Candidal intraocular infection typically manifests as a fluffy white choroidal or retinal lesion with white snowball-like vitreous opacities.
- *Aspergillus* causes necrotizing chorioretinitis or endophthalmitis via hematogenous spread, usually from the lung.
- Coccidioidal intraocular inflammation may appear as chronic iridocyclitis, iris granuloma, choroiditis, or chorioretinitis.

## Associated Features

### Candidal Intraocular Infection

- Usually seen in immunocompromised or diabetic individuals, those with indwelling catheters, intravenous drug users, presence of candidemia.

### *Aspergillus* Endogenous Endophthalmitis

- Usually seen in immunocompromised individuals but rarely in healthy patients.

### Coccidioidal Intraocular Inflammation

- Systemic coccidioidal infection, endemic in American Southwest, including the San Joaquin Valley in California, northern Mexico, and Argentina.

Fungal endophthalmitis is a vision-threatening condition that presents diagnostic and management challenges. Fungi can reach the eye hematogenously or exogenously, as a complication of trauma or surgery or from extension from periocular and orbital sites.

## CANDIDA

### INTRODUCTION

Candidemia is the most common cause of endogenous fungal endophthalmitis. *Candida albicans*, an important nosocomial pathogen, is the most common *Candida* species.<sup>1</sup>

### EPIDEMIOLOGY AND PATHOGENESIS

*Candida* yeasts reach the eye most commonly by hematogenous spread to the choroid or rarely from direct inoculation following ocular trauma or surgery.<sup>1,2</sup> With candidemia, the organisms typically cause one or more foci of chorioretinitis, which may progress to involve the vitreous, where it is then termed endophthalmitis. Predisposing conditions include diabetes, intravenous drug use, prolonged hospitalization, history of major surgery, bacterial sepsis requiring broad-spectrum systemic antibiotics, hyperalimentation, chronic indwelling catheters, and immunosuppression secondary to organ transplantation, chemotherapy or acquired immunodeficiency syndrome (AIDS).<sup>1,3</sup>

**Fig. 7.11.1 25-Year-Old Woman With a History of Intravenous Drug Abuse With Endogenous *Candida* Endophthalmitis.** (A) Montage fundus color photo. Note vitreous haze from vitritis, vitreous white fluffy lesion overlying fovea (arrow), multiple round white lesions inferiorly at the level of posterior hyaloid (arrowheads), hyperemic and edematous disc. (B) External color photo. Note needle tracks along veins (arrow) and injection sites (arrowheads) at the forearm.

### OCULAR MANIFESTATIONS

The typical clinical features are white fluffy chorioretinal lesions with overlying vitritis. There may be focal vitreous involvement, which appear as small, white, snowball-like opacities, or there may be diffuse involvement manifesting as dense vitreous haze (Fig. 7.11.1). At least half the patients have multiple lesions, and two-thirds have bilateral involvement. There

may be satellite lesions and retinal vascular sheathing. Iridocyclitis of variable severity is a frequent finding, and hypopyon may be present.<sup>1</sup>

## HISTOPATHOLOGY

Eyes with *Candida* endophthalmitis have acute, progressive inflammation in the vitreous cavity (Fig. 7.11.2). Involvement of the retina and uvea usually is mild, though foci of retinal damage from invasion of the organisms can be seen. Regarding the distribution of fungi, yeasts are mainly localized to the vitreous abscess with the presence of few organisms in the retina. Retinal vessel wall invasion is not seen in *Candida* endophthalmitis.<sup>4</sup>

## ASPERGILLUS

### EPIDEMIOLOGY AND PATHOGENESIS

*Aspergillus* endophthalmitis is a devastating ocular infection. *Aspergillus fumigatus* is the most common pathogen. *Aspergillus* species are saprophytic molds that grow in soil and decaying vegetation with airborne spores. Exposure is relatively common, but infection is rare. Risk factors are chronic pulmonary disease, intravenous drug use, and severe immunocompromise, especially after liver transplantation, but it has even been reported in immunocompetent patients without predisposing conditions.<sup>5</sup>

**Fig. 7.11.2** Vitreous Biopsy Specimen From a Patient With *Candida* Endophthalmitis. Note *Candida* yeasts and hyphae in wet mount (KOH) preparation.

*Aspergillus* fungi reach the eye via hematogenous spread to the choroid, and *Aspergillus* is the most common fungal species isolated in postoperative fungal endophthalmitis cases.<sup>2,5</sup>

## OCULAR MANIFESTATIONS

Patients usually present with rapid-onset severe pain and decreased visual acuity. Often the central macula is involved. A confluent, yellowish macular infiltrate begins in the choroid and subretinal space (Fig. 7.11.3A). A layering of inflammatory exudate may occur in the subhyaloid space.<sup>5</sup>

The degree of retinal involvement is variable from subretinal or subhyaloid infiltrate to vascular occlusion and full-thickness retinal necrosis with intraretinal hemorrhages. Vitreous involvement is seen later in the disease process, and eventually the anterior segment can be involved.

## HISTOPATHOLOGY

Eyes with *Aspergillus* infection have acute inflammatory cells in the retina, subretinal space, and choroid. Although fungi can be seen in the vitreous (Fig. 7.11.3B), involvement of the retina and choroid is common, and the hyphae are often present in the subretinal space, under the retinal pigment epithelium, and in other locations (Fig. 7.11.4). Retinal and choroidal vessel wall invasion by fungal elements is also noted, and hemorrhage is present in all retinal layers and occasionally even in the choroid.<sup>4</sup>

## FUSARIUM

### EPIDEMIOLOGY AND PATHOGENESIS

*Fusarium* species are ubiquitous filamentous molds commonly found in soil and on plants. *Fusarium* is the most common fungal pathogen in endophthalmitis resulting from keratitis with contiguous spread, and the most common cause of keratomycosis in the southeastern United States. Rare cases of *Fusarium* endophthalmitis have been reported after cataract surgery. Endogenous *Fusarium* endophthalmitis is rare and almost all cases involve disseminated infection in immunocompromised patients, either secondary to leukemia or other severe systemic conditions.

## OCULAR MANIFESTATIONS

Exogenous *Fusarium* endophthalmitis tends to be more localized, with the inflammation and fungal mass confined to the anterior chamber, pupillary space, and anterior vitreous, but it can extend to diffuse vitritis and posterior segment involvement (Fig. 7.11.5). Endogenous *Fusarium* endophthalmitis is characterized by a fibrinous reaction in the anterior chamber, vitritis, and a variable degree of retinal ischemia and necrosis.<sup>6</sup>

**Fig. 7.11.3** Young Man With a History of Intravenous Drug Abuse With Endogenous *Aspergillus* Endophthalmitis. (A) Color fundus photo. Note vitreous haze from vitritis and macular lesion with retinal hemorrhages. (B) Vitreous biopsy specimen. Note multiple *Aspergillus* filaments in undiluted vitreous specimen staining with alcian blue.

## COCCIDIODES IMMITIS—OCULAR COCCIDIOIDOMYCOSIS

*Coccidioides immitis* is a dimorphic fungus found in soil and is endemic to the San Joaquin Valley of central California, Arizona, and parts of Central and South America. The incidence of coccidioidomycosis is increasing in

**Fig. 7.11.4** Lens Capsule Specimen From a Patient With Chronic *Aspergillus* Endophthalmitis. Note multiple *Aspergillus* filaments, which stain with Gomori's methenamine silver. (Courtesy Narsing A. Rao, MD, and Daniel V. Vasconcelos-Santos, MD.)

**Fig. 7.11.5** 70-Year-Old Woman With *Fusarium* Endophthalmitis. Note vitreous haze from vitritis and severe vasculitis (arrowheads). (Courtesy Lucia Sobrin, MD.)

the United States. Infection follows inhalation of the highly infectious, dust-borne spores and usually results in pulmonary disease, but *Coccidioides* endophthalmitis may present with no concomitant systemic involvement.

The typical posterior infection is a multifocal choroiditis with numerous scattered, discrete, yellow–white lesions less than one disc diameter in size (Figs. 7.11.6 and 7.11.7). Vascular sheathing, retinal hemorrhage, serous retinal detachment, and vitreous haze may occur in the acute phase of infection.<sup>7</sup>

## CRYPTOCOCCAL ENDOPHTHALMITIS

*Cryptococcus neoformans* is a yeast with worldwide distribution frequently found in pigeon feces. Infection is acquired through the respiratory tract. It usually causes an opportunistic infection, especially of the central nervous system in AIDS or debilitated patients. The most frequent presentation of ocular cryptococcosis is a multifocal choroiditis with discrete, yellow–white lesions of variable size. Other findings may include optic nerve involvement, vascular sheathing, and exudative retinal detachment. Cryptococcal infection may rarely progress to endophthalmitis (Fig. 7.11.8).<sup>8</sup>

## HISTOPLASMA ENDOPHTHALMITIS

*Histoplasma capsulatum* is a dimorphic fungus endemic to the southeastern and central United States. In the immunocompetent individual, the acute infection is usually self-limited with a localized granulomatous reaction. Disseminated histoplasmosis in the immunocompromised individual may lead to generalized systemic disease with involvement of multiple organs. Rare cases of *Histoplasma* endophthalmitis have been reported in immunocompromised patients, especially in those with AIDS, but it has also been described in immunocompetent patients. Ocular manifestations include granulomatous chorioretinitis with variable degrees of anterior chamber and vitreous involvement. Patients may develop diffuse intraretinal and subretinal exudation and hemorrhage with focal subretinal granulomas as well as tractional and rhegmatogenous retinal detachment.<sup>9</sup>

## DIAGNOSIS OF FUNGAL ENDOPHTHALMITIS

A high index of suspicion is critical because the clinical diagnosis of fungal endophthalmitis is usually based on the ophthalmological appearance in combination with the presence of fungemia or predisposing factors. In the absence of known fungemia, cultures of blood, catheter tips, wounds, and/or body fluids should be obtained. Cardiac imaging studies may be necessary to rule out the presence of septic emboli. A diagnostic vitreous aspirate with special stains and culture (see Figs. 7.11.2, 7.11.3B, 7.11.4, 7.11.7, and 7.11.8) is the gold standard for diagnosis, but the sensitivity is only approximately 44%.<sup>10</sup>

**Fig. 7.11.6** 36-Year-Old Man With *Coccidioides* Choroiditis and Pneumonitis. (A) Fundus color photo. Note multiple yellow choroidal lesions (arrowheads). (B) Bronchoalveolar lavage, histopathology specimen. Note *Coccidioides* spherule (arrow). (Courtesy J. Michael Jumper, MD.)

**Fig. 7.11.7 Undiluted Vitreous Specimen From 64-Year-Old Man With *Coccidioides* Endophthalmitis.** Note mature spherules of *Coccidioides* that stain with Gomori's methenamine silver. (Courtesy Narsing A. Rao, MD, and Daniel V. Vasconcelos-Santos, MD.)

**Fig. 7.11.8 Vitreous Specimen From 69-Year-Old Man With Endogenous *Cryptococcal* Endophthalmitis.** Note cryptococcal staining with alcian blue (arrowheads).

More recently, polymerase chain reaction (PCR) detection of fungal species in vitreous specimens has shown high sensitivity and specificity, enabling the rapid diagnosis of fungal endophthalmitis.<sup>11</sup> Vitrectomy is more likely to yield positive culture results as the primary diagnostic method rather than anterior chamber or vitreous tap, especially in cases of *Aspergillus* endophthalmitis.<sup>10</sup> In cases of endophthalmitis that result from keratitis, corneal biopsy with calcofluor white stain and cultures are useful in establishing the diagnosis. Histopathological examination of the vitreous and any associated epiretinal membranes with periodic acid–Schiff (PAS) and Gomori methenamine silver staining is helpful in the diagnosis of intraocular coccidioidomycosis because serological testing and cultures are frequently negative. A high index of suspicion is important, especially in endemic areas.<sup>7</sup> In cryptococcal cases, India ink and mucicarmine staining of vitreous samples, epiretinal membranes, and retinal biopsy samples are essential to reveal the characteristic broad capsule.<sup>8</sup>

### BOX 7.11.1 Differential Diagnosis of Fungal Endophthalmitis

Endogenous bacterial endophthalmitis  
Toxoplasma retinochoroiditis  
Primary intraocular lymphoma  
Cytomegalovirus retinitis  
Posterior uveitis

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis of fungal endophthalmitis is given in Box 7.11.1.

## TREATMENT OF FUNGAL ENDOPHTHALMITIS

Systemic antifungal therapy should be administered to all individuals with endogenous fungal infections of the eye. Corticosteroid therapy should be avoided. The treatment with amphotericin B has been limited because of significant nephrotoxicity and relatively poor intraocular penetration. Newer antifungal drugs such as fluconazole and voriconazole have broad-spectrum antifungal activity, more than 90% oral bioavailability, and good ocular penetration.<sup>12</sup> Voriconazole is a newer azole compound that has shown the most promise, as therapeutic concentrations for most *Candida* and *Aspergillus* species are achieved in the vitreous, and it can be used in infections that are resistant to fluconazole and other agents.<sup>13</sup> Systemic treatment with either fluconazole (12 mg/kg loading dose, then 6–12 mg/kg daily) or voriconazole (6 mg/kg for 2 doses, then 4 mg/kg twice daily) is usually used for at least 4–6 weeks, with the final duration dependent on the response observed using repeated ophthalmological examinations.<sup>12</sup> Despite its considerable systemic toxicity, amphotericin B can be used for the most severe infections when treatments with other agents have failed.

Although a standard treatment protocol does not exist, in cases of macula-threatening involvement and in cases of *Aspergillus* endophthalmitis, intravitreal injection of an antifungal drug should be performed in addition to initiation of systemic therapy. Voriconazole (100 µg/0.1 mL) or amphotericin B (5 µg/0.1 mL) is given by intravitreal injection. Voriconazole is considered safer than amphotericin B, but there is more experience with amphotericin B, which also has the advantage of having a longer half-life after intravitreal injection. The need for repeated injections is dependent on the response to therapy.<sup>5,12,13</sup>

Early surgical intervention with pars plana vitrectomy is recommended for cases of fungal endophthalmitis with significant vitreous involvement, in cases of suspected aspergillosis, or if there is no significant improvement with intravitreal treatment.<sup>10,14</sup> Sampling the vitreous at the time of vitrectomy can provide important culture and PCR data to identify the pathogen and guide treatment.<sup>10</sup> Vitrectomy is combined with administration of intravitreal agents. Outcomes of early vitrectomy in addition to systemic antifungals have been favorable for cases of *Candida* and *Aspergillus* endophthalmitis.<sup>14</sup> The half-life of antifungal agents administered directly into the vitreous at the time of vitrectomy is shortened, and repeated administration may be necessary if there is evidence of persistent infection.

A team approach involving both a retina specialist and an infectious disease specialist is essential to ensure the most efficacious and safe treatment, as close monitoring for systemic manifestations and side effects is essential.

## COURSE AND OUTCOME

Early diagnosis and initiation of systemic and intravitreal treatment is important for reduction of both mortality and ocular morbidity.

Close follow-up is needed with examinations at least twice weekly initially to evaluate response to treatment. *Candida* endophthalmitis is associated with severe visual loss (20/200 or less) in 33%–60% of patients and final visual acuity of 20/50 or better in 42%.<sup>10</sup> The visual prognosis of *Aspergillus* endophthalmitis is worse, despite aggressive treatment, because of early macular involvement, with visual acuity 20/200 or worse in the majority of the eyes and 20/50 or better in only 7%.<sup>5</sup>

Factors associated with severe visual loss are poor visual acuity at presentation, lesions located in posterior pole, and the development of retinal detachment, which has been reported to occur in as many as 29% of patients. Early vitrectomy within 1 week of presentation has been associated with a lower incidence of retinal detachment and better visual outcomes.<sup>10,14,15</sup>

# Ocular Toxoplasmosis

Daniel Vitor Vasconcelos-Santos

# 7.12

**Definition:** Ocular toxoplasmosis is a recurrent retinochoroiditis caused by *Toxoplasma gondii* and represents the most common cause of infectious posterior uveitis worldwide.

## Key Features

- Unilateral focal retinochoroiditis.
- May manifest either early after primary systemic infection or later, after reactivation of intraretinal *Toxoplasma gondii* cysts.
- Diagnosis made primarily on a clinical basis and supported by laboratory investigations.

## Associated Features

- Most commonly a unilateral focal retinochoroiditis.
- Multiple and even bilateral active lesions may occur in immunocompromised individuals and in the setting of recently acquired infection.
- Significant inflammatory involvement of the vitreous.
- Retinal vasculitis.
- Optic disc edema.
- Anterior uveitis.
- Treatment – combination therapy with antiparasitic drugs and corticosteroids.

## INTRODUCTION

Toxoplasmosis is caused by *Toxoplasma gondii*, an apicomplexan parasite infecting one-third of the human population.<sup>1,2</sup> Toxoplasmosis represents the main cause of infectious posterior uveitis worldwide and may lead to vision-threatening complications, including severe retinochoroidal scarring, vitreous opacities, cataract, glaucoma, and choroidal neovascularization.<sup>3-5</sup>

## ORGANISM AND LIFE CYCLE

*Toxoplasma gondii* is one of the most successful obligate intracellular parasites, capable of infecting virtually any warm-blooded animal and establishing lifelong chronic infection.<sup>2,6</sup> Sexual reproduction of the parasite only occurs in the intestine of members of the Felidae family, among which the domestic cat represents the archetypical definite host for *T. gondii*.<sup>1,7</sup>

The organism has several evolutive forms. The tachyzoite is the active proliferating form, present in intermediate and definite hosts during acute infection. It is able to penetrate any nucleated cell and circulate all over the body, leading to cell lysis, direct tissue damage, and subsequently to a strong, potentially destructive immune response. Under the pressure of the immune system, tachyzoites differentiate into bradyzoites, forming tissue cysts.<sup>8,9</sup> These are latent forms and may persist indefinitely in host tissues (such as striated muscle and central nervous system—particularly the neurosensory retina), without eliciting significant inflammatory response. These tissue cysts are also refractory to currently available antiparasitic drugs, which is the reason that chronic *T. gondii* infection cannot be cured. Tissue cysts can rupture later and release bradyzoites that convert to tachyzoites, leading to disease reactivation, especially in the retina.<sup>2,8</sup>

The definite host becomes infected by either ingesting meat containing tissue cysts/tachyzoites from intermediated hosts or by ingesting sporulated oocysts present in the soil and shed in the feces of feline hosts.<sup>7</sup> Once in the intestine, the parasite invades enterocytes and reproduces asexually

and sexually.<sup>9</sup> Sexual reproduction allows prolific genetic recombination, potentially facilitating emergence of more virulent strains of the parasite.<sup>10</sup> Felines shed oocysts 3–18 days after oral infection, and each of these animals contaminates the environment with millions of oocysts per day. These mature in the soil into sporulated oocysts, becoming infective after 1–21 days and persisting in the environment for up to 18 months.<sup>7,9</sup>

As for definite hosts, *T. gondii* also infects intermediate hosts (including humans) by means of oocysts contaminating the soil, water, or vegetables or by bradyzoite-containing cysts present in the tissues of other hosts. Transplacental transmission in recently infected hosts, and more rarely laboratory accidents and organ transplantation, are other possible modes of infection.<sup>2,7</sup>

## EPIDEMIOLOGY

*T. gondii* is a ubiquitous parasite and is present in all continents, with higher rates of human infection in humid and tropical areas and in those with larger populations of domestic cats.<sup>1,7</sup> In the United States, antibodies to *T. gondii* are found in nearly 20% of the human population. In France and in South America this rate reaches up to 80%.<sup>1-3</sup> Seroconversion increases with age and is particularly problematic in pregnant women because of risk of vertical transmission in the setting of recently acquired acute toxoplasmosis. In the first trimester of pregnancy, rates of transplacental infection are around 10%–25% and progressively increase to reach 60%–80% in the third trimester.<sup>11</sup> Conversely, the potential severity of fetal sequelae typically decreases during pregnancy.<sup>12</sup>

Human infection is classically associated with ingestion/handling of raw or undercooked meat containing tissue cysts of *T. gondii*.<sup>7</sup> Recent evidence, however, supports the importance of water contaminated with oocysts as an emerging source of infection.<sup>1,13-15</sup> Vegetables and fruits may also be contaminated by oocysts and lead to human infection.<sup>7</sup>

Congenital toxoplasmosis used to be blamed for most cases of ocular toxoplasmosis.<sup>1,16,17</sup> This is in line with the large proportion (approaching 80%) of infected infants displaying retinochoroidal lesions.<sup>18-20</sup> However, more reliable data on the relatively low incidence of congenital toxoplasmosis, in addition to increased documentation of postnatally acquired disease (often asymptomatic), support the hypothesis that the latter may be far more important than previously suspected.<sup>13,21-23</sup> Still, the rates of ocular involvement following postnatally acquired toxoplasmosis fall between 2% and 3%<sup>17,24,25</sup> but may be as high as 20% in some areas.<sup>1,22</sup>

## PATHOLOGY AND PATHOGENESIS

Histopathologically, active ocular toxoplasmosis manifests as a focal retinochoroiditis, with necrotizing granulomatous inflammation of the retina associated with reactive granulomatous involvement of the choroid, vitreous, and even the anterior uveal tract. Parasites may be seen as free tachyzoites or tissue cysts within the necrotic focus (Fig. 7.12.1) but also in the adjacent retina.<sup>26,27</sup> Mononuclear inflammatory infiltrates surrounding retinal blood vessels are also frequently seen. Disruption/migration of the retinal pigment epithelium (RPE) is commonly observed.<sup>26,28</sup> The inflammatory process can extend to underlying sclera. A retinochoroidal scar is left (chorioretinal adhesion) after resolution of inflammation, with variable proliferation of RPE. Intact *T. gondii* cysts without reactive inflammation may be found in histologically normal retina.<sup>29,30</sup>

Pathogenesis depends on a delicate balance between host immunity and parasite virulence.<sup>2,30</sup> Immunoimmaturity associated with congenital toxoplasmosis is clearly associated with more extensive systemic/ocular lesions, some of which are related to disruption of embryogenesis and fetogenesis.<sup>12</sup> Immunosuppressed adults are also more susceptible to severe systemic and ocular disease.<sup>2,4</sup>

**Fig. 7.12.1 Histopathology of Toxoplasmic Retinochoroiditis, Showing Extensive Necrosis of the Neurosensory Retina and Retinal Pigment Epithelium (RPE).** The choroid displays reactive diffuse granulomatous inflammation (hematoxylin-eosin stain, original magnification 400×). Toxoplasmic cysts are seen within the necrotic retina, staining with Gomori's methenamine silver (GMS, inset). (Courtesy N. Rao, University of Southern California.)

In immunocompetent individuals with postnatal infection, however, parasite proliferation can be contained earlier by the immune system, limiting the extent of tissue damage. A small number of these individuals develop ocular disease soon after seroconversion, but a higher proportion of them have local recurrences later in life, associated with cysts that were previously seeded even in normal-looking retina.<sup>1,30</sup> Rupture of such cysts releases bradyzoites that convert to tachyzoites, establishing active parasite proliferation locally, with subsequent cell lysis and release of cytotoxic mediators and eliciting a vigorous necrotizing granulomatous response that may also lead to further tissue damage.<sup>30,31</sup> Hypersensitivity to retinal antigens may also play a role in maintaining intraocular inflammation during recurrences.<sup>32</sup>

The first line of immune defense to *T. gondii* after oral infection is in the gastrointestinal tract. In addition to the barrier effect of enterocytes, the local innate immune response driven by a variety of cells including polymorphonuclear leukocytes, macrophages, B/T lymphocytes, and natural killer (NK) cells may at least partially contain parasite proliferation both directly and indirectly.<sup>33</sup> These cells, in addition to others such as dendritic cells, also help to trigger the adaptive immune response, the main responsible for successful control of *T. gondii* infection.<sup>6,34,35</sup>

The adaptive immune response is coordinated by CD4+ T lymphocytes and macrophages. This Th1 (T-helper-1) reaction leads to the synthesis of various proinflammatory cytokines, particularly interleukin-12, interferon- $\gamma$ , and tumor-necrosis-factor- $\alpha$ , which act synergistically to contain parasite replication. CD8+ T lymphocytes are also cytotoxic to infected cells. A Th2 response counterbalances the proinflammatory Th1 pathway, down-regulating the protective immunity to *T. gondii*.<sup>6,34,35</sup>

Parasite virulence is also an important determinant of pathogenesis.<sup>2</sup> In this regard, *T. gondii* has three main genetic lineages with different virulence/geographic distribution.<sup>36,37</sup> Type I parasites are highly virulent, eliciting a strong proinflammatory response that is potentially associated with severe tissue damage. Type II parasites are the least virulent and under immune pressure promptly encyst in tissues and establish chronic infection in susceptible hosts. Type III parasites are also less virulent.<sup>38</sup> In addition to these three canonical genotypes, atypical recombinant genotypes emerging from sexual recombination in the definite host have been increasingly observed in highly endemic areas such as South America and in association with outbreaks of severe systemic/ocular disease worldwide.<sup>39–42</sup>

## CLINICAL MANIFESTATIONS

### Systemic Disease

Immunocompetent individuals with postnatally acquired toxoplasmosis are frequently asymptomatic. Some develop a mononucleosis-like syndrome, manifested with fever, malaise, and variable lymphadenopathy. Only a small number evolve to severe systemic disease, including pneumonitis,

hepatitis, myocarditis, and even encephalitis. Immunocompromised individuals, especially those with acquired immune deficiency syndrome (AIDS), are susceptible to life-threatening disease either at primary infection or during reactivation, particularly in the form of neurotoxoplasmosis (toxoplasmic encephalitis).<sup>2,4</sup>

Congenital toxoplasmosis is associated with a large spectrum of systemic manifestations ranging from intrauterine death or severe malformations to a neonatal infectious syndrome including anemia, thrombocytopenia, cutaneous rash, hepatitis, pneumonitis, myocarditis, and even encephalitis.<sup>2,12</sup> Hydrocephalus or microcephaly, intracranial calcifications, mental retardation, and retinochoroiditis represent the Sabin's tetrad, occurring in less than 10% of newborns with congenital toxoplasmosis.<sup>12,19</sup> The leading clinical manifestation, however, is retinochoroiditis, present in up to 80% of newborns at birth.<sup>5,18,19</sup>

### Ocular Disease

Postnatally acquired toxoplasmosis is rarely associated with ocular disease in immunocompetent individuals early after seroconversion,<sup>1,16</sup> but reactivation of intraretinal cysts may lead to retinochoroiditis any time later in life. The active retinochoroidal lesion presents clinically as a whitish or yellowish exudate involving the inner retina with adjacent retinal edema. Typically the lesion arises at the margins (or close to) a pre-existent retinochoroidal scar (satellite lesion, Figs. 7.12.2 and 7.12.3) but may also present as an isolated focal lesion (Fig. 7.12.4).<sup>3,43,44</sup> The lesion progresses to involve full thickness of the retina with reactive inflammatory thickening of the underlying choroid (see Fig. 7.12.3).

Inflammatory cellular infiltration of overlying vitreous is invariably present and may lead to granulomatous precipitates on the posterior hyaloid and even to denser vitreous opacities or bands. Active lesions associated with more severe vitreous haze can typically display a "headlight-in-the-fog" aspect on fundus examination. Perivascular sheathing, particularly of venules, is also commonly seen, even distant to the primary inflammatory focus. Adjacent periarterial lipidic exudates (*Kyrieleis arteriolitis*) can also be found (see Fig. 7.12.4). Perivascular exudative lesions may complicate with vascular (especially venular) occlusions, leading to further retinal edema or hemorrhages. Larger active lesions are often associated with macular or optic nerve head edema. Reactive involvement of the anterior uveal tract may also be seen, as a granulomatous or nongranulomatous iridocyclitis. Intraocular pressure is elevated in 10%–30% of these cases. Toxoplasmic retinochoroidal scars are clinically polymorphic but frequently have some degree of pigmentation, indicating RPE hyperplasia or hypertrophy. Some can be so atrophic as to show the underlying sclera.<sup>3,22</sup>

Congenital toxoplasmosis is associated with retinochoroidal lesions in up to 80% of infected newborns, mostly in the macular area and even bilaterally. The typical wagon-wheel scar in the macula (Fig. 7.12.5) strongly suggests congenital toxoplasmosis, but other variably pigmented lesions can be present elsewhere. Active satellite or isolated focal lesions may also be

seen, either early after birth or any time later in life, with features virtually indistinguishable from those of reactivations associated with postnatally acquired disease. Large necrotizing lesions can also rarely develop.<sup>5,18,19</sup>

In addition to satellite and isolated focal lesions, ocular toxoplasmosis may have atypical forms of presentation.<sup>44</sup> Outer retinal toxoplasmosis is characterized by minimal vitreal involvement and punctate infiltrates primarily in the outer retina, often leading to serous retinal detachment. Toxoplasmic neuroretinitis occurs in the setting of juxtaglial exudative lesions, culminating in edema of the optic nerve head and even in a macular star.<sup>43,44</sup> Extensive, multifocal, and even bilateral active lesions may present similarly to a picture of viral retinitis (Fig. 7.12.6) and are more frequent in immunosuppressed and elderly individuals and in those with recently acquired infection, either congenital or postnatal.<sup>3,4,23,43,45</sup> Toxoplasmic intraocular inflammation without concomitant necrotizing

retinochoroiditis is relatively rare and may manifest as isolated anterior uveitis, retinal vasculitis, and optic neuritis. These atypical forms of presentation have been increasingly reported in the presence of recent postnatally acquired disease.<sup>4,46</sup>

## DIAGNOSIS

The diagnosis of ocular toxoplasmosis is essentially clinical, based on the presence of a focal necrotizing retinochoroiditis (see Figs. 7.12.2, 7.12.3, and

**Fig. 7.12.2 Fundus Appearance of Toxoplasmic Retinochoroiditis With a Typical Active Satellite Lesion Adjacent to Pigmented Retinochoroidal Scars.**

**Fig. 7.12.3 Fundus and Tomographic Appearance of Toxoplasmic Retinochoroiditis.** An exudative toxoplasmic lesion is seen nasally to the optic disc in association to vitreous haze and perivenular sheathing (top). Vertical optical coherence tomography section of the lesion (green line) discloses nodular hyperreflective retinal focus with posterior shadowing. Fusiform thickening of underlying choroid can also be appreciated (bottom).

**Fig. 7.12.4 Fundus Appearance of Toxoplasmic Retinochoroiditis, With an Active Exudative Lesion in the Absence of Retinochoroidal Scars (Isolated Focal Lesion).** Inset shows surrounding retinal edema and periarteriolar exudates (Kyrleis arteriolitis).

**Fig. 7.12.5 Fundus Appearance of Congenital Toxoplasmosis.** A typical “wagon-wheel” scar is seen in the right macula.

**Fig. 7.12.6 Fundus Aspects of Atypical Toxoplasmic Retinochoroiditis.** Multiple and extensive exudative toxoplasmic lesions simulating herpetic retinitis are seen in a patient with AIDS.

7.12.4), often associated with an adjacent or distant retinochoroidal scar. Variable inflammation of vitreous, retinal blood vessels, optic nerve, and anterior segment is also frequently present.<sup>3,43,44</sup>

Serological tests are supportive, revealing in most cases only the presence of IgG antibodies to *T. gondii* and denoting chronic infection. Absence of specific IgG and IgM virtually excludes the possibility of toxoplasmosis, whereas their presence, particularly in significant titers, indicates recently acquired disease, which may also be suggested by low avidity of specific anti-*T. gondii* IgG antibodies. For congenital toxoplasmosis, the diagnosis is sealed by IgM and/or IgA and/or persistently high levels of IgG antibodies to *T. gondii* after 12 months of life.<sup>2,3,12,43</sup>

In cases of less typical presentation, invasive investigations may be employed, including assessment of intraocular antibody synthesis and polymerase chain reaction (PCR) of ocular fluids.<sup>43,47–49</sup> The former is possible through calculation of the Goldmann–Witmer or Witmer–Desmonts coefficient based on the correlation between titers of specific antibodies to *T. gondii* in aqueous humor or serum versus the globulin titers in the same fluids.<sup>49</sup> A high coefficient indicates intraocular synthesis of anti-*T. gondii* antibodies, and a low coefficient has an opposite interpretation, although this may also occur in the setting of severe disruption of the blood–ocular barrier.

In yet uncertain cases, PCR of aqueous humor or vitreous can be an invaluable tool to definite diagnosis of toxoplasmosis and other infectious etiological factors. Particularly for toxoplasmosis, positivity of vitreous

**TABLE 7.12.1 Differential Diagnosis of Primary or Recurrent Toxoplasmic Retinochoroiditis**

#### Infectious

##### Bacterial

Syphilis  
Tuberculosis  
Bartonellosis (neuroretinitis, focal retinitis, and angiomatous lesions)  
Lyme disease  
Endogenous endophthalmitis  
Others

##### Viral

Acute retinal necrosis/necrotizing herpetic retinopathy  
CMV retinitis  
Progressive outer retinal necrosis  
Others

##### Fungal

Candidiasis (particularly endogenous endophthalmitis)  
Aspergillosis  
Others

##### Parasitic

DUSN  
Toxocariasis  
Others

#### Noninfectious

##### Associated with systemic disease

Behçet’s disease  
Sarcoidosis  
Others

##### Primarily not associated with systemic disease

Serpiginous/ampiginous choroiditis and others  
Multifocal choroiditis and panuveitis  
Punctate inner choroidopathy  
Multiple evanescent white dots syndrome  
Unilateral acute idiopathic maculopathy  
Others

#### Neoplastic

Primary vitreoretinal lymphoma  
Others

CMV, Cytomegalovirus; DUSN, diffuse unilateral subacute neuroretinitis.

samples often exceeds that of aqueous humor samples but is lower than for herpes family viruses.<sup>47–49</sup>

Imaging modalities including echography, fluorescein or indocyanine green angiography, and optical coherence tomography are seldom decisive to the diagnosis but may otherwise help to better delineate the vitreal and retinochoroidal changes (see Fig. 7.12.3) and to document or assess local complications such as vascular occlusions, macular edema, and choroidal neovascularization.<sup>3,43,50</sup>

## DIFFERENTIAL DIAGNOSIS

Infectious, noninfectious, and even neoplastic entities are considered in the differential diagnosis of ocular toxoplasmosis (Table 7.12.1).<sup>43</sup>

In newborns with suspicion of congenital disease, exclusion of infections by agents of the TORCHS acronym (*T*Oxoplasmosis, *R*ubella, *C*ytomegalovirus, *H*erpes, *S*yphilis) is mandatory. Other less common congenital infections simulating toxoplasmosis include West Nile virus fever, acute lymphocytic choriomeningitis, and more recently Zika virus, the latter particularly in the setting of microcephaly.<sup>51</sup> Tumors such as retinoblastoma and retinocytoma and noninflammatory entities such as retinochoroidal colobomata and persistent hyperplastic vitreous are also to be considered in the differential diagnosis of these young children.<sup>3,43</sup>

Primary or recurrent toxoplasmic retinochoroiditis in older children or adults may be either congenital or postnatally acquired and should be equally differentiated from infectious (bacterial, viral, fungal, parasitic), noninfectious (associated or not with a systemic disease), and neoplastic entities (see Table 7.12.1).<sup>3,43</sup>

## THERAPY

Toxoplasmic retinochoroiditis may be self-limited in some patients. The decision to treat should thus be based on several factors, including individual immune status and location, size, and local repercussion of the active lesion (Box 7.12.1).<sup>3,4,52</sup>

In immunocompetent patients, small, peripherally located, active lesions and those with no significant exudation may be observed

### BOX 7.12.1 Main Factors Influencing Treatment Decision on Active Toxoplasmic Retinochoroiditis

- Immune status of the individual
- Location and size of the active lesion
- Presence of macular and/or optic disc edema
- Degree of vitritis and of decreased vision
- Clinical course
- Special situations (newborns, pregnant women, drug allergy)
- Adverse effects of antiparasitic drugs and corticosteroids

initially. Worsening of intraocular inflammation and the development of sight-threatening complications indicates the necessity to treat.<sup>3,4,52</sup>

Treatment is a combination of antiparasitic drugs/systemic corticosteroids. Topical corticosteroids, mydriatic, and hypotensive agents are also employed as needed. The most widely used regimen (and still considered the standard, so-called classic therapy) is the association of sulfadiazine and pyrimethamine.<sup>2,52,53</sup> All patients on pyrimethamine should be monitored with periodic complete blood counts and should also receive supplementation with folic acid (not *folic acid*) to prevent bone marrow suppression.<sup>2,53</sup> In the setting of allergy or intolerance to sulfonamides, clindamycin or azithromycin may be utilized. Relevant details on main antiparasitic drugs for the treatment of toxoplasmosis are summarized in Table 7.12.2.

Oral corticosteroid (0.5–1 mg/kg/day of prednisone or equivalent) is also typically used in a tapering regimen, with favorable effect on inflammation of the vitreous, retina, and optic nerve.<sup>3,4,52</sup> It should be initiated at least 24 hours after starting antiparasitic drugs and tapered off before stopping them. Caution should be taken to avoid corticosteroids without concomitant antiparasitic coverage because of risk of progressive/devastating intraocular inflammation. The use of pericocular or intravitreal depot corticosteroids is relatively contraindicated for the same reasons. Treatment duration is often 5–6 weeks but may be longer for larger active lesions and persistent intraocular inflammation.<sup>4</sup> Resolution of the active lesion is typically centripetal, with progressive flattening of the margins and decreased exudation.<sup>3</sup> Lesion pigmentation may be delayed, and is a variable and unreliable feature.

Alternative antiparasitic drugs in different regimens have also been proposed (Table 7.12.2).<sup>3,52</sup> Intravitreal therapy with clindamycin has also been reported, with single or repeated injections through the pars plana of 1 mg of clindamycin and 0.4 mg of dexamethasone.<sup>54</sup> Some of these alternative regimens are regarded as comparable to the classic antiparasitic therapy in small randomized clinical trials.<sup>55,56</sup> However, experimental in vivo and in vitro studies and those enrolling immunosuppressed patients and neonates with congenital toxoplasmosis are still largely supportive of the classic therapy as opposed to alternative antiparasitic regimens.<sup>2,53</sup> These regimens may be particularly useful in the setting of drug allergy (sulfadiazine is the main culprit) and other adverse effects and in some specific situations in the presence of smaller and less exudative lesions.

Immunosuppressed individuals with active toxoplasmic retinochoroiditis should always be treated, because of its progressive nature with a high risk of complications and even loss of the eye in this population. Neonates with congenital toxoplasmosis are also invariably treated during the first year of life, receiving antiparasitic drugs regardless of the presence of retinochoroidal lesions. Pregnant women with documented recent seroconversion also need treatment with spiramycin (even in the absence of retinochoroiditis) to decrease the risk of vertical transmission. Because spiramycin does not cross the placenta, when fetal infection is confirmed by either PCR of amniotic fluid or ultrasound, other antiparasitic drugs are to be employed.<sup>2,53</sup> Reactivations during gestation may be initially followed if the posterior pole is not threatened, due to the very low risk of fetal infection.

Laser photocoagulation and even cryotherapy have been suggested for extramacular chronically exudative lesions in individuals nonresponsive to or not tolerating systemic therapy.<sup>3,52</sup> Their efficacy is unclear, however, and recurrences may still occur out of treated area. Other surgical modalities, such as pars plana vitrectomy and phacoemulsification (phaco), are employed mostly for management of complications, including persistent vitreous opacities, epiretinal membranes, retinal detachment, and cataract.<sup>3,52</sup>

Secondary prophylaxis with sulfamethoxazole/trimethoprim (800/160 mg 3×/week or every other day) has been shown to decrease risk of recurrences in immunocompetent adults.<sup>57</sup> This may be useful in

TABLE 7.12.2 Main Antiparasitic Drugs for the Treatment of Toxoplasmosis

Drug and Dosage	Precautions and Observations
Sulfadiazine 1 g qid in adults 50–100 mg/kg/day in children	Caution and dose correction for hepatic renal failure Contraindicated in G6PDH deficiency Hydration and alkalinization of urine may prevent crystalluria Avoid at the end of gestation (risk of kernicterus) Hypersensitivity and allergies demand suspension Stevens–Johnson syndrome possible but rare Bone marrow suppression in <0.1%
Pyrimethamine Loading dose of 100 mg, followed by 25–50 mg/day 1 mg/kg/day in children	Caution in hepatic or renal failure Contraindicated in first trimester (teratogenic) Common gastrointestinal disturbances Risk of bone marrow depression demands concomitant use of folic acid (5–7.5 mg/day or 15 mg 3×/week) and periodic CBC monitoring
Clindamycin 300 mg qid 10–25 mg/kg/day in children	Caution in hepatic or renal failure Common gastrointestinal disturbances Risk of pseudomembranous colitis (suspend if bloody diarrhea)
Azithromycin 250–500 mg/day 5 mg/kg/day in children	Food decreases oral absorption Gastrointestinal disturbances in less than 10% May be used in pregnancy
Sulfamethoxazole/trimethoprim 800 mg/160 mg bid 40–50 mg/8–10 mg/kg/day in children	Better tolerated than classic therapy but probably less effective Caution and dose correction in case of hepatic/renal failure Contraindicated in G6PDH deficiency Avoid during gestation (risk of teratogeny and kernicterus) Risk of sulfa hypersensitivity Bone marrow suppression uncommon
Spiramycin 1.5 million IU (500 mg) qid	High levels in placenta Safest antiparasitic drug in pregnancy Limited intraocular penetration Gastrointestinal disturbances and hypersensitivity
Atovaquone 750 mg qid 30 mg/kg/day in children	Caution with liver failure Food increases drug absorption Maculopapular rash in up to 20% No safety studies concerning gestation/lactation

CBC, Complete blood count; G6PDH, glucose-6-phosphate dehydrogenase; IU, international units.

New Delhi: Jaypee-Highlights; 2013. p. 671–7; Kim SJ, Scott IU, Brown GC, et al. Interventions for toxoplasma retinochoroiditis: a report by the American Academy of Ophthalmology. Ophthalmology 2013;120:371–8.

individuals with multiple recurrences threatening the central macula and in the immunosuppressed. Even though the ideal duration is not definitely established, recent evidence suggests that prophylaxis for 12 months may prevent recurrences for up to 2 years thereafter.<sup>57</sup>

Primary prophylactic measures are essential in seronegative women right before and during pregnancy and in immunosuppressed patients. These measures include:

- Avoiding ingestion of raw/undercooked meat (freezing at –20°C/–4°F overnight also destroys tissue cysts).
- Drinking only well-filtered or boiled water.
- Carefully washing vegetables/fruits before consumption.
- Using gloves and washing hands/kitchen utensils after manipulating meat/soil.
- Avoiding contact with felines and their feces (even in soil or litter boxes).<sup>2,3,7</sup>

Monthly serological screening of susceptible women during pregnancy is also highly recommended.<sup>2,53,58</sup>

## COURSE AND PROGNOSIS

Toxoplasmic retinochoroiditis is a recurrent disease, with up to two-thirds of patients developing reactivations later in life.<sup>1,3,59</sup> These are more common in congenital than in postnatally acquired toxoplasmosis and occur especially in the first year after the previous episode. Some patients, however, sustain long-lasting disease remission.<sup>59</sup>

Prognosis depends on the immune status and age of the patient and on the size and location of the lesion(s). Local complications such as

persistent vitreous opacities, macular edema, epiretinal membranes, extensive retinochoroidal scarring, choroidal neovascularization, optic atrophy, and even retinal detachment may be associated with significantly decreased vision.<sup>3,4,23,45</sup>

# Posterior Parasitic Uveitis

Dipankar Das, Jyotirmay Biswas

# 7.13

**Definition:** Posterior parasitic uveitides encompass a number of parasitic infestations caused by different parasites. Various vectors spread the diseases, and areas of endemicity vary from region to region in the world. Clinical manifestations include characteristic ocular lesions, dermatological involvement and other extraocular sites affection. Parasitic diseases other than toxoplasmosis are described here.

## Key Features

- Ophthalmic and systemic examination is essential for the diagnosis of posterior parasitic diseases.
- Early diagnosis of these conditions is necessary to prevent ocular morbidity.
- Food hygiene and vector control is important in preventing the spread of the diseases.
- Parasitic diseases like toxocariasis is found in children.

## INTRODUCTION

Parasitic infections can produce severe damage to various ocular tissues, especially the uvea, thereby causing significant visual morbidity. It is important for ophthalmologists to be aware of the clinical presentation of the parasitic infestations for prompt diagnosis and management. Proper diagnoses of ophthalmic parasites can help to save vision and sometimes lives. Therefore, it is important to have appropriate coordination between clinicians, pathologists, and parasitologists for effective management of ocular parasites.

## OCULAR CYSTICERCOSIS

Ocular cysticercosis is the most common tapeworm infection caused by *Cysticercus cellulosae*, which is a larval form of the pork tapeworm *Taenia solium*.<sup>1-3</sup> Sometimes it may be caused by beef tapeworm. Consumption of undercooked pork and use of contaminated vegetables or water by humans can cause this infection.<sup>1,2</sup> Cysticercosis primarily affects the central nervous system (CNS), subcutaneous tissue, external eye structures, muscles, and intraocular structures like vitreous and retina.<sup>1,2</sup> Cysticercosis is found in worldwide distribution with about 50 million people being affected by this parasitic disease.<sup>1-3</sup> It is prevalent in South and Central America, Eastern Europe, Mexico, the Indian subcontinent, Russia, and the Philippines. It is rare in Great Britain and United States.<sup>1-3</sup>

## CLINICAL PRESENTATION

Intraocular cysticercosis may be asymptomatic in the early stages when the parasite is small. Ophthalmic cysticercosis can cause features such as loss of vision, periorbital pain, scotoma, and photopsia. Cysticercosis may present as neurocysticercosis or subcutaneous or muscular cysticercosis. The cyst may be localized to the subconjunctival space or orbit or may invade the globe and present in anterior or posterior segment.<sup>3</sup>

Intravitreal cysticercosis appears as a translucent white cyst with a dense spot formed by the invaginated scolex. The shape and undulating movements are typical. The cyst may remain asymptomatic when it is small and alive. Subretinal cysticercosis may present as acute central retinitis with retinal edema and subretinal exudates. The subretinal organism eventually develops into a cyst (Fig. 7.13.1). The macular area is the common site where the subretinal cysticercus lodges because of the vascularity of the area. B-scan ultrasound with identification of an intralesional scolex is

Fig. 7.13.1 Intravitreal Cysticercus With Cyst Isolated in Pathology.

**Fig. 7.13.2 B-Scan Ultrasound Showing a Scolex in a Case of Intraocular Cysticercosis.**

diagnostic in cases of intraocular cysticercosis (Fig. 7.13.2). The movements of the cysticercus are easily seen through the thin macular tissues. The cyst often migrates into the vitreous, leaving behind a chorioretinal scar in this area. One mode of presentation is that of fibrinous anterior uveitis with secondary glaucoma; the uveitis resolves with removal of the cyst. The posterior segment manifestation of ocular Cysticercosis can be variable, ranging from mild to intense vitritis with evidence of cystic larvae. Retinal break, rhegmatogenous retinal detachment, exudative retinal detachment, chorioretinal scar, or atrophy with epimacular membrane can be seen. Optic atrophy, optic disc edema, and sometimes atypical optic neuritis may be the remote presentation. Because of CNS involvement, the patient may have epileptiform seizures and mild fever.<sup>3,4</sup>

Diagnosis becomes difficult when the parasite dies, because it produces marked inflammatory response presenting as pan uveitis with dense opacification of the vitreous. In severe cases the patient may present with a painful blind eye. In these cases, a B-scan ultrasound is useful in confirming the diagnosis. B-scan usually demonstrates the complete cyst with an eccentric high reflective opacity (scolex). Other diagnostic modalities include neuroimaging such computed tomography (CT) imaging or magnetic resonance imaging (MRI) of brain and orbit. Coin-shaped lesion(s) with perilesional edema can be picked up in an MRI scan of the brain.<sup>1-4</sup> Serologically, cysticercosis can be diagnosed by precipitin reaction, complement fixation, or indirect hemagglutination assay.<sup>5</sup> Anticysticercus antibodies can be detected by enzyme-linked immunosorbent assay (ELISA) in approximately 80% cases of neurocysticercosis, 57% of ocular cysticercosis, and 50% with myocysticercosis.<sup>5</sup>

## TREATMENT

Surgical removal of the cyst is recommended. Intraocular cysticerci are removed either by external sclerotomy with choroidal incision or via pars plana vitrectomy.<sup>4,5</sup> Transscleral approach is used for subretinal cysts positioned anterior to the equator. The pars plana vitrectomy or transvitreal approach is used for intravitreal and subretinal cysts located posterior to the equator.<sup>4</sup> If there are both intraocular and CNS cysticercus cysts, then the complete intraocular cyst must be removed surgically, first followed by antiparasitic medication and corticosteroid.<sup>4,5</sup> Only use of antihelminthic medication in intraocular cysticercosis in the first attempt without surgical removal can kill the intraocular live parasite and thereby can induce severe intraocular reaction causing eventual blindness.<sup>4</sup> Albendazole and praziquantel are principal antiparasitic drugs that are used in treating neurocysticercosis and primary external ocular disease.<sup>4-10</sup>

## OCULAR TOXOCARIASIS

Ocular toxocariasis is caused by the dog roundworm *Toxocara canis*. It usually affects young patients. The various clinical presentations of the disease are:

### Chronic Endophthalmitis

This can present as a vitreous abscess or a dense white inflammatory mass usually associated with a retinal detachment. It may be associated with

**Fig. 7.13.3 Peripheral Toxocara Lesion.**

a granulomatous response in the anterior chamber and a hypopyon. The acute inflammatory phase is followed by a cicatricial stage.

## Posterior Pole Granuloma

Initially presents with a hazy vitreous and signs of acute inflammation with the posterior pole granuloma seen as an ill-defined hazy mass with surrounding vitreous inflammation. The media clears as the inflammation subsides. The spherical granulomatous mass is white or gray, and traction bands are seen running from the mass to the surrounding retina.

## Peripheral Granuloma

It is seen as a dense white localized inflammatory mass in the retinal periphery. Localized traction on the retina results in a fold or tractional detachment extending from the mass to the posterior pole. This can cause dragging of the macula toward the granuloma (Fig. 7.13.3).

## Atypical Presentations

These include optic nerve head inflammation, motile subretinal nematode, and diffuse chorioretinitis.

## DIFFERENTIAL DIAGNOSIS

- Retinoblastoma.
- Retinopathy of prematurity.
- Familial exudative vitreoretinopathy.
- Coats' disease.
- Persistent hyperplastic primary vitreous.
- Endogenous endophthalmitis.

## ANCILLARY TESTING

A serum ELISA titer of 1:8 is sufficient to support a diagnosis of ocular toxocariasis if the patient also has compatible clinical features.

## TREATMENT

Antihelminthics such as thiabendazole and diethylcarbamazine have a limited role. In cases with severe inflammation, topical corticosteroids, cycloplegics, and systemic corticosteroids may be necessary. Vitrectomy is indicated in cases of tractional retinal detachment.

## ONCHOCERCIASIS

This infection is caused by the filarial worm *Onchocerca volvulus* or *Onchocerca caecutiens*. The disease is widely endemic in tropical Africa and

tropical parts of the Americas. The disease is spread by the black (biting) fly (*Simulium*), which freely breeds in the rivers. The blindness caused by onchocerciasis is known as river blindness. About half a million people in the world are blind or partially blind due to onchocerciasis. Systemic manifestations consist of skin nodules (lymphadenopathy). Ocular manifestations are very common and include swelling of eyelids, proptosis, thickening of the conjunctiva, and nummular keratitis. It is not rare to see microfilaria wandering in the anterior chamber and vitreous cavity.

Uveoretinal inflammation is the most important pathology of onchocerciasis so far as visual loss is concerned. The toxins liberated from the dead worms induce the uveal pathology. Plastic iritis associated with edema of iris stroma produces the spongy pumice stone appearance of the iris. Light brown exudative deposits in the lower part of the anterior chamber produce an inverted pear-shaped appearance of the pupil that is considered a characteristic ocular sign of the disease. Chorioretinal inflammation leading to atrophy of the neural tissue with consecutive optic atrophy is the ultimate cause of blindness. Ophthalmoscopic examination of the fundus shows clumping of retinal pigment, atrophy of choriocapillaris, and subretinal fibrosis. Glaucoma and cataract may be complications of uveoretinal inflammation. The effective treatment of onchocerciasis is with ivermectin, diethylcarbamazine (Hetrazan) and suramin (Antrypol).

### GNATHOSTOMIASIS

This is due to a parasite known as *Gnathostome*, ingested by people by eating semicooked fish, usually found in dirty shallow drains. Cases of gnathostomiasis had been reported from the eastern region of undivided India including present-day Bangladesh.<sup>2</sup> Clinical features of the disease may be cutaneous and visceral, including ocular involvement. Ocular manifestations of the disease occur due to migration of the larvae as well as host response to the toxins. The most common presenting feature is anterior uveitis.<sup>3,5,9-13</sup> Other features include lid swelling, iritis, iris atrophy, iris holes (Fig. 7.13.4), and rarely glaucoma. Intravitreal gnathostomiasis is a very rare entity. Macular scarring or retinal tear with choroidal hemorrhage near the optic disc points to the posterior retina as a possible route of entry to the eye. The worm roams in the eye, causing retinal hemorrhage and subsequent chorioretinitis (Fig. 7.13.5). Surgical removal of the live worm may be done while it is visible in the anterior chamber.

### DIFFUSE UNILATERAL SUBACUTE NEURORETINITIS

Diffuse unilateral subacute neuroretinitis (DUSN) is also called unilateral wipe-out syndrome. It can be caused by a number of motile, nematode roundworms including *Toxocara canis*, *Gnathostoma*, *Brugia malayi*, *Ancylostoma caninum*, and the trematode *Altaria*.<sup>1-3,11,14-16</sup> Males are more frequently affected than females. Nematodes in DUSN may invade the skin

and migrate hematogenously to retinochoroidal complex.<sup>2,3</sup> These small worms are thought to induce toxic, inflammatory, and autoimmune reaction to the choroid and overlying retina. DUSN can present with either early or late stage manifestations.<sup>4,5,17</sup> Patients may present with central and paracentral scotomas, floaters, and visual field defect without any significant ocular pain. In the early stage, optic disc edema, mild to moderate vitritis, subretinal, multifocal yellow gray-white lesions are seen in the fundus with papillitis.

Late stages include optic nerve atrophy, retinal arteriolar narrowing, increased internal limiting membrane reflections (Oréface's sign), and subretinal tunnels (Garcia's sign) with retinal pigment epithelium (RPE) degeneration.<sup>1,17</sup> A relative afferent pupillary defect (RAPD) may be present on the affected eye. DUSN is now believed to be caused also by small number of different nematode larvae.<sup>15</sup> The first pathological change secondary to nematode larva infestation presents as granulomas in the whole globe.<sup>1</sup>

There have been variable sizes of worms detected and reported, with longer worms leaving a tract of coarse clumping of pigment epithelium.<sup>1,16</sup> The shorter worms predispose to leave focal, chorioretinal atrophic scars. The focal chorioretinal white spots are an immune response to a secretion or excretion from the worm. Worms, regardless of species, have been observed in the eye for up to 3 years. The diagnosis is mostly clinical. The live worm may not be visible on many occasions. Fluorescein angiography (FA) may show an increase in background choroidal fluorescence, diffuse changes in RPE, and capillary dye leakage near the optic nerve.

Fig. 7.13.4 *Gnathostoma* Worm Migrating Through Iris Creating Iris Hole.

Fig. 7.13.5 Retinal and Vitreal *Gnathostoma* With Wet Mount Preparation of the Parasite.

Indocyanine green angiography (ICGA) is sometimes useful to locate the lesions as hypofluorescent spots and corresponding choroidal infiltration and inflammation. Electrophysiological tests such as electroretinogram (ERG) and electro-oculogram (EOG) are helpful for ancillary support for the diagnosis. In ERG, A:B ratio can be normal in early stages of the disease, but B wave can be defective when significant retinal involvement is seen. The inner retina is more involved than the outer retina.<sup>4,17</sup> EOG may show reduced response in moderate to late involvement.

Optical coherence tomography (OCT) is an important tool to demonstrate degeneration of retinal nerve fiber layer (RFNL) and thinning of the macula. Here also, inner retinal volume is more affected than the outer retinal volume. In some cases there may be loss of foveal depression. Laboratory diagnosis should include eosinophils count for the nematode infections.

Other diseases that should be ruled out include syphilis, sarcoidosis, and toxoplasmosis. Optic neuritis, pars planitis, and some of the white dot syndromes need to be excluded for making the diagnosis. A macular cyst has also been an associated finding in DUSN.<sup>1,3,16</sup> Management of DUSN depends on whether the worm is visible. Visible live nematodes are treated with retinal photocoagulation. Systemic treatment involves 400 mg albendazole daily for one month with oral corticosteroid 1 mg/kg/day in tapering dose for one month. The course of the disease depends on the disease stage. Early detection stops the vision loss effectively.<sup>1-3,6-9,16,18,19</sup>

## AMEBIASIS

Infection by *Entamoeba histolytica* is quite frequent in tropical countries. It is estimated that about 20% of rural populations are the victims of this parasitic intestinal disease, which causes dysentery, hepatitis, and liver abscess.

Ocular involvement of amebiasis involves:

- Anterior and posterior uveitis.
- Recurrent vitreous hemorrhage.
- Retinal periphlebitis.

In none of the affected cases, however, could *Entamoeba histolytica* be isolated from the eye. The presumptive diagnosis was based on coexistent disease process and definite improvement of the eye condition after antiamebic treatment.

## GIARDIASIS

Intestinal infection by *Giardia lamblia* is common in the Indian subcontinent. Keratitis, uveitis, extensive chorioretinitis, and retinal hemorrhages in patients with giardiasis have been reported. Some of the common presentations of giardia are anterior uveitis, choroiditis, and retinal pigment changes. All the reported cases responded well to the treatment of giardiasis.

## MALARIA

There are about 300 million cases of malaria worldwide annually, and 30 million persons from nonendemic countries visit malaria-endemic countries. Thus there is a significant possibility of traveler's malaria. The parasite responsible for malaria in humans belongs to Plasmodium family *P. vivax* (tertian malaria), *P. malariae* (quartan malaria), *P. falciparum* (subtertian malaria), and *P. ovale*. Ocular complications are more common in *P. falciparum* infection. Almost all the structures of the eye may be involved in malaria.

Conjunctival hyperemia, subconjunctival hemorrhage, conjunctival pigmentation, dendritic ulcer, interstitial keratitis, uveitis, vitreous hemorrhage, retinal hemorrhage, retinal detachment, optic neuritis, paralysis of extraocular muscles, and orbital cellulitis have been reported.<sup>4,5,10,17</sup> Retinal hemorrhage is considered to be due to rheological complications—the parasitized erythrocytes tend to clump along the vessel wall leading to occlusion.<sup>7</sup> Other ocular lesions include retinal hemorrhages, transient ocular nerve palsies, orbital edema, choroiditis, retinal embolism, papilledema, paralysis of the pupillary light reflex, and accommodation. The presence of ocular lesions in malaria indicates poor prognosis, especially in patients

with cerebral malaria.<sup>7,11</sup> Therefore, a patient with unexplained large retinal hemorrhages should always be investigated thoroughly for malaria, especially in an endemic country such as India.

## LEISHMANIASIS

Leishmaniasis is widespread in central and eastern Asia, Africa, and a few countries in Europe. The disease is caused by the protozoan *Leishmania*, which is transmitted to humans by sand fly (*Phlebotomus*). Three distinct types have been recognized:

- Visceral leishmaniasis is caused by *Leishmania donovani* and is responsible for kala-azar.
- Cutaneous leishmaniasis is caused by *Leishmania tropica* and is manifested as granulomatous sores in the exposed parts of the body, known as oriental sore.
- Nasopharyngeal leishmaniasis (espundia) is caused by *Leishmania braziliensis* and is mostly prevalent in South America.

Characteristic features of kala-azar are persistent irregular fever for a long period, enormous enlargement of the spleen, moderate enlargement of liver, and marked degree of anemia. The diagnosis is made by identifying *L. donovani* in smears from spleen and bone marrow puncture.

## OCULAR MANIFESTATION

Retinal hemorrhages occur perhaps due to severe anemia.<sup>6</sup> Thrombosis of the central retinal vein also may occur. Ocular involvements of post kala-azar dermal leishmaniasis include episcleral nodules that may lead to deep corneal vascularization. Post kala-azar uveitis also has been reported.<sup>7,8,12,13,20</sup> In oriental sore, tiny ulcerating papules may be found in the eyelids at the site of the bite by the sand fly. It may be associated with conjunctivitis. In espundia, the ulcer is limited to the face and mucous membrane of the anterior third of the nasal septum. In severe cases, the ulcer may destroy the nose and the eyelids.

## PEDIATRIC PRESUMED TREMATODE INFECTION

This has been reported in patients from South India who were exposed to pond water. The causative parasite was identified as *Philophthalmus*. The external body surface, referred to as a tegument, is made up of an external plasma membrane and an internal trilaminar plasma membrane.<sup>9,14</sup> Dermatitis may be an associated extraocular feature. The ocular manifestations are subconjunctival nodules, anterior chamber nodules, and granulomatous uveitis (but rarely panuveitis or posterior uveitis). Histologically, the nodules have eosinophilic infiltration along with chronic inflammatory cells and a specific inflammatory reaction known as Splendore Hoeppli phenomenon. This phenomenon is characterized by a central deposit of granular, acellular eosinophilic material surrounded by eosinophilic leukocytes, epithelioid cells, histiocytes, and lymphocytes. Occasionally, teguments of parasite may also be seen.

## OPHTHALMOMYIASIS

This is a condition where the eye or adnexa are invaded by maggots (larvae). Cattle, sheep, horse, deer, and humans are the known hosts. Eggs are deposited by the flies in the lid margins or on the conjunctiva, producing local inflammatory changes (ophthalmomyiasis externa). In ophthalmomyiasis interna, larvae pass through their second stage and can penetrate the eye and orbit causing tissue damage (Fig. 7.13.6). Small conjunctival hemorrhages may occur because of tissue damage from oral hooks. Subretinal tracts are representative of mechanical injury to retinal pigment epithelium.<sup>5</sup> The death of the larva can cause uveitis.

# Uveitis Related to HLA-B27 and Juvenile Idiopathic Arthritis–Associated Uveitis

7.14

Carlos E. Pavesio

## UVEITIS RELATED TO HLA-B27

**Definition:** Ocular inflammation associated with the HLA-B27 antigen.

### Key Features

- Acute and recurrent unilateral nongranulomatous anterior uveitis.
- Ocular pain and photophobia.
- Ciliary injection.
- Often severe anterior uveitis with fibrin deposition or hypopyon.
- Frequent posterior synechiae.

### Associated Features

- Often ankylosing spondylitis.
- Sometimes reactive arthritis.

## JUVENILE IDIOPATHIC ARTHRITIS-ASSOCIATED UVEITIS

**Definition:** Uveitis associated with chronic arthritis of at least 6 weeks duration in a child younger than 16 years of age when other causes have been excluded.

### Key Features

- Asymptomatic, bilateral, nongranulomatous anterior uveitis.
- Symptomatic in some acute forms and in the presence of complications.
- Posterior synechiae, cataract, glaucoma, and less frequently cystoid macular edema (CME) are complications.
- Screening very important for early detection and treatment.

### Associated Features

- Oligoarthritis.
- Antinuclear antibodies.

## UVEITIS RELATED TO HLA-B27

### INTRODUCTION

The most common form of uveitis worldwide is acute, unilateral, and nongranulomatous, involving only the anterior segment (acute anterior uveitis [AAU] or iridocyclitis). Most affected patients are systemically well, but studies suggest that between 40% and 50%—and perhaps up to 80%<sup>1</sup>—are positive for HLA-B27. Those who manifest associated systemic inflammation usually have ankylosing spondylitis (AS); a smaller number have inflammatory bowel disease, reactive arthritis, or psoriatic arthropathy.

The locus for human leukocyte antigens (HLA) is on chromosome 6p. HLA types are autosomally inherited, partly explaining the increased familial risk of AAU and AS in those carrying HLA-B27. The antigen is polymorphic with more than 31 subtypes.<sup>2</sup> In Northern Europeans, 90% of those who are HLA-B27–positive express HLA-B\*2705 (which may be the primary ancestral HLA-B27 subtype)<sup>3</sup>; this subtype is more common in men. All common subtypes are associated with both AAU and AS, exceptions being B\*2706 or B\*2709.<sup>4</sup>

The prevalence of HLA-B27 differs markedly between populations (more common in white races), and this fact is reflected in a wide disparity in the incidence of related inflammatory disease.<sup>5</sup> In Bantus in Zaire, the prevalence of HLA-B27 is very low at 0.7%<sup>6</sup>; in the United Kingdom and United States the figure is 6%–8%, rising to 14% in Finland,<sup>7</sup> and maximally, 50% in the Haida Indians of Canada, where one in 10 men has AS.<sup>8</sup>

### PATHOGENETIC MECHANISMS

The presence of HLA-B27 predisposes to AAU, AS, and reactive arthritis, but the lifetime risk of AAU for those who are HLA-B27–positive is only 1%.<sup>9</sup> Therefore it is clear that further provocation is necessary to trigger AAU in this susceptible population. There are well-known associations between infection with some Gram-negative bacteria and *Chlamydia* and AAU. The original theories of molecular mimicry by homologous regions on HLA-B27 and bacterial receptors<sup>10</sup> have not been fully elucidated. It is becoming increasingly clear that AAU is a polygenic disease; it is known that some polymorphisms of the tumor necrosis factor alpha promoter region are protective against AAU in HLA-B27–positive patients, whereas others are proinflammatory<sup>11</sup> and knowledge of other cytokine polymorphisms important to the induction of attacks of inflammation is advancing.<sup>3</sup>

Evidence from numerous studies suggests a strong genetic component in the pathogenesis of acute anterior uveitis,<sup>3,12,13</sup> with increasing evidence that genes other than HLA-B27 influence the risk of developing AAU. Recent genome-wide studies of large cohorts of patients detected three non-major histocompatibility complex (MHC) loci: IL23R, the intergenic region 2p15, and ERAP1, which were associated with AAU and AS ( $p < 5 \times 10^{-8}$ ).<sup>3,14</sup> In addition, five loci harboring the immune-related genes IL10-IL19, IL18R1-IL1R1, IL6R, the chromosome 1q32 locus harboring KIF21B, and EYS were also associated at a “suggestive level of significance.”

### CLINICAL FEATURES AND LABORATORY INVESTIGATIONS

The paradigm for HLA-B27–associated AAU is a young man with acute-onset unilateral ocular pain and photophobia with redness and visual blur. Visual acuity in the affected eye is usually somewhat (but not markedly) reduced. Ocular examination is characteristically difficult because of photophobia. There is marked ciliary injection and severe AAU with small keratic precipitates inferiorly, anterior chamber (AC) cells 2–4+, often with fibrinous coagulum inferiorly, and sometimes with an hypopyon. Fibrin may form a web within the AC, the aqueous humor may be plasmoid (full of leaked plasma proteins so that normal thermal flow is sluggish), and incipient posterior synechiae are common (Fig. 7.14.1). The intraocular pressure is reduced, usually less than 10 mm Hg. Cells in the anterior

**Fig. 7.14.1 Acute Anterior Uveitis After Partial Mydriasis.** There are residual synechiae, a pupillary pigment imprint on the anterior lens capsule, and an inferior fibrinous coagulum.

vitreous are common. Macular edema is not uncommon, and optic nerve head swelling is occasionally seen.

HLA-B27 is positive in many patients with AAU. Notably, in those under 40 with acute unilateral recurrent AAU without mutton-fat keratic precipitates, the concordance with HLA-B27 is so high<sup>15</sup> that laboratory confirmation of positivity may be unnecessary. A recent report described a small series of patients over the age of 70 who had a very aggressive picture of acute anterior uveitis at presentation.<sup>16</sup>

Recurrent AAU is common, usually in the same eye. Frequently, patients have several recurrences of ipsilateral AAU followed by several in the other eye. Some patients develop bilateral uveitis, and a minority go on to develop chronic unremitting inflammation. Poorly controlled inflammation and chronicity are associated with poorer outcomes.<sup>17</sup> Pupillary block will require laser iridectomy or (because these tend to block), surgical iridectomy. Glaucoma induced by peripheral anterior synechiae (PAS) requires medical or surgical treatment. Raised intraocular pressure, although identified in about one-quarter of all presentations,<sup>18</sup> is more common in chronic-phase disease. HLA-B27–associated AAU carries a worse prognosis than HLA-B27–negative uveitis.<sup>19</sup> However, despite multiple recurrences and/or chronic disease, bilateral visual loss is fortunately very uncommon.<sup>20</sup>

Posterior segment involvement in HLA-B27–associated uveitis is very uncommon but can be so severe as to mimic infective endophthalmitis.<sup>21</sup> In rare cases severe uveitis with a serous retinal detachment might develop in HLA B27–positive patients and may be complicated by protracted hypotony, macular edema, and poor visual outcome.<sup>22</sup> Retinal vasculitis, papillitis, cystoid macular edema, and epiretinal membrane formation are all seen occasionally.<sup>23</sup> Associated systemic disease is more common in this group.<sup>24</sup>

## ASSOCIATED SYSTEMIC DISEASE

Associated systemic inflammation can be identified in up to 78% of patients.<sup>25</sup> The AAU often precedes diagnosis of an arthropathy, and the ophthalmologist must identify the relevant disease and refer if necessary. Some patients presenting with AAU have had AS diagnosed already; others should be specifically asked about chronic lower back pain with morning stiffness and referred for investigation and treatment (Fig. 7.14.2).

Reactive arthritis (Reiter's syndrome) may unusually present with conjunctivitis. The classic clinical scenario is a man with nonaxial lower limb arthropathy and/or enthesitis with circinate balanitis and a vesiculopustular rash, sometimes keratinized, on the palms and soles, known as keratoderma blennorrhagicum. There may also be mouth ulcers.

Psoriasis is extremely common and therefore will be randomly associated with uveitis in some patients. However, the minority who have associated arthropathy have a specific risk of acute or chronic anterior uveitis. Characteristically the distal small-joint polyarthritis is destructive (Fig. 7.14.3), sometimes leading to very severe finger damage with characteristic

**Fig. 7.14.2 Fusion of the Sacroiliac Joint Space With Sclerotic Change in Ankylosing Spondylitis.**

**Fig. 7.14.3 Characteristic Dactylitis in Psoriatic Arthropathy.**

swan-neck deformities. A genuine association between nonarthritic psoriasis and uveitis is unproven, but in the absence of arthropathy, any uveitis tends to be more chronic, and posterior segment involvement with or without retinal vasculitis may be seen. This contrasts with psoriatics who are HLA-B27–positive<sup>26</sup> or those with spondyloarthropathy,<sup>27</sup> where more characteristic AAU is seen.

Inflammatory bowel disease (IBD), most commonly Crohn's disease, is associated with uveitis, but as for psoriasis, in those who are HLA-B27–negative this is commonly bilateral and chronic and may involve the posterior segment.<sup>28</sup> Crohn's disease can be associated with AS in the absence of HLA-B27,<sup>29</sup> but nongranulomatous anterior uveitis does not appear to be. Interestingly, patients with both psoriatic and IBD-related arthropathy are more likely to have axial than peripheral arthropathy if HLA-B27–positive.<sup>27</sup> HLA-B27 appears capable of modifying the disease pattern in those with a pre-existing underlying arthropathy, and it is tempting to suggest the same for associated uveitis.

## TREATMENT AND PREVENTION

Untreated AAU tends to be self-limiting within a few weeks, leaving substantial posterior synechiae and often PAS. Subsequent attacks frequently result in seclusio pupillae, pupil block glaucoma, and painful blindness. In contrast, early and effective treatment eliminates pain, more rapidly resolves inflammation, and minimizes complications.

Immediate and diligent mydriasis and cycloplegia is imperative; rapid analgesia results and incipient synechiae are usually broken. Subconjunctival procaine, atropine, and epinephrine can break recalcitrant synechiae, especially with warm compresses. Frequent, strong, topical corticosteroid is highly effective. Although the level of evidence for topical corticosteroid potency is poor,<sup>30</sup> the clinical impression is that intensive prednisolone acetate 1%, which has a very high anterior chamber penetration,<sup>31</sup> is most useful; its introduction has markedly reduced the need for subconjunctival corticosteroid injection. Topical nonsteroidal anti-inflammatory

drugs (NSAIDs) are inadequate to treat any substantial uveitis. However, oral NSAIDs have been found useful in some instances.<sup>32</sup> In severe cases, both daily subconjunctival and single-dose periocular depot corticosteroid can be helpful, and rarely, high-dose oral corticosteroid achieves control. If fibrin deposition is extreme and pupil block likely, intracameral tissue plasminogen activator has been used successfully<sup>33</sup> but not widely, as there is a substantial risk of hyphema. Topical corticosteroid treatment is tapered according to response, but overly aggressive dose reduction can lead to a flare-up of inflammation. Most attacks require 6–10 weeks of topical corticosteroid. Associated macular edema usually subsides with topical corticosteroid alone.

Some go on to develop chronic inflammation, either anterior or panuveitis. Inadequate topical corticosteroid will inevitably lead to destructive complications. In some, oral immunosuppression is needed. Early treatment has been recommended.<sup>34</sup> Some patients are frustrated by multiple recurrences and ask about prophylaxis. The evidence base is poor, but in small groups, both sulphasalazine<sup>35</sup> and methotrexate<sup>36</sup> have been considered useful. Further, much larger studies are necessary.

A large retrospective study suggested that infliximab and adalimumab reduced the rate of uveitis, while the frequency of uveitis in patients with spondyloarthritis treated with etanercept remained unchanged.<sup>37</sup> A large meta-analysis, involving the data from four placebo-controlled studies with anti-tumor necrosis factor (TNF) agents in AS (two with etanercept and two with infliximab) and three open-label studies, showed that infliximab and etanercept seem to reduce the incidence of uveitis versus placebo, and further, infliximab appeared to be more effective than etanercept, even though the difference between them did not reach statistical significance.<sup>38</sup>

Adalimumab was also evaluated from data of 1250 patients with active AS in a prospective open-label study. Adalimumab achieved an approximately 50% reduction in uveitis flares.<sup>39</sup>

Although, there are no prospective head-to-head randomized studies comparing efficacy of anti-TNF $\alpha$  agents in HLA-B27 uveitis management, infliximab and adalimumab are generally accepted to be more effective than etanercept.<sup>40</sup>

Reports of the efficacy of golimumab have recently appeared, but conclusive data is not yet available.<sup>41</sup>

## JUVENILE IDIOPATHIC ARTHRITIS

### INTRODUCTION

Juvenile idiopathic arthritis (JIA) is defined as a chronic arthritis of at least 6 weeks' duration in a child younger than 16 years of age when other causes of arthritis have been excluded.<sup>42</sup> It is the most common cause of uveitis of childhood in Europe and North America.<sup>43,44</sup> It has an estimated prevalence of 113 per 100 000 children in the United States,<sup>45</sup> and the annual incidence is 10–20 per 100 000,<sup>46</sup> similar to that seen in the United Kingdom. The highest rates occur in Scandinavia, but rates are lower in southern Europe.

The criteria published by the International League of Associations of Rheumatology (ILAR) covers all childhood arthritides under the name JIA.<sup>42</sup> Apart from unifying the name, it has established that the disease duration for the diagnosis should be 6 weeks and includes juvenile ankylosing spondylitis (JAS), juvenile psoriatic arthritis (JPsA), and arthropathy associated with IBD under this broad definition.

The new classification of JIA has divided it into seven subtypes, defined after the first 6 months of disease.

Oligoarthritis is the most common subtype (50%–70%), followed by polyarthritis (30%), with the great majority being rheumatoid factor (RF) negative. Systemic onset and enthesitis-related arthritis each occur in about 5% of patients. These figures are valid for populations of European ancestry, and ethnic differences have been reported, with the polyarticular form being more common in nonwhite populations.<sup>47</sup>

### PATHOGENETIC MECHANISMS

The pathogenesis of JIS is not well understood, and the evidence indicates that JIA is a multifactorial and polygenetic disease, but it does seem that the genetic contribution is modest, which is evidenced by the modest increase in risk to family members of JIA cases and multiple genetic associations involving mainly the MHC locus.<sup>48</sup>

The chronic and remitting course has led to assumption that problems with control of the regulatory processes over effector cells may lead to loss of immune homeostasis, and the role of the regulatory T cells has also been considered as a potential determinant of the course of the disease.<sup>48,49</sup>

## CLINICAL PICTURE

*Oligoarthritis* occurs predominantly in young girls and affects four or fewer (usually large) joints, with the knee being the most commonly involved, during the first 6 months of disease.<sup>50</sup>

*Rheumatoid factor-negative polyarthritis* has a chronic course, affecting both small and large joints, with more than four joints involved in the first 6 months of disease. It is more common in girls, with a higher age at onset.

*Psoriatic arthritis* may have characteristics of both oligo- and polyarticular disease, but the occurrence of psoriasis and arthritis helps establish the diagnosis.<sup>42</sup> These patients do not show an increased frequency of HLA-B27 and rarely will manifest sacroiliitis or lumbosacral spinal arthritis.<sup>50</sup>

*Enthesitis-related arthritis* is a chronic inflammation of entheses and particularly involves the foot, knee, and pelvis. It is common in boys, with the uveitis being symptomatic and occurring in older adolescents and adults. Most of these patients will have HLA-B27 and will eventually develop sacroiliitis and lumbosacral spinal disease.

## UVEITIS IN JIA

As much as 80% of anterior uveitis in the pediatric population is associated with JIA.<sup>51</sup> A recent meta-analysis revealed that the cumulative incidence of JIA-associated uveitis is 8.3%; in the oligoarticular group is 12.4%, in the polyarticular group is 4.3%, and in patients with systemic onset, 1.8%.<sup>52</sup>

## RISK FACTORS

Risk factors for the development of uveitis include oligoarticular arthritis type, early age at onset of arthritis, positive antinuclear antibodies (ANAs), negative RF, and female sex.<sup>53,54</sup> A meta-analysis showed that oligoarticular onset tripled the risk when compared to polyarticular onset, a positive ANA nearly tripled the risk of oligoarticular onset patients, and unexpectedly, female sex alone was a weak risk factor.<sup>52</sup> Even though ANAs are a risk factor for developing uveitis, their levels are not predictive of uveitis recurrences.<sup>55</sup>

Factors associated with long-term complications include severe disease at presentation,<sup>55</sup> short interval between onset of arthritis and the diagnosis of uveitis,<sup>56</sup> male sex,<sup>57</sup> presence of complications at initial presentation,<sup>58</sup> and early age at onset of uveitis.<sup>53</sup> Male sex and shorter interval between onset of arthritis symptoms and the diagnosis of uveitis were found to be the only significant risk factors for severe uveitis at diagnosis,<sup>59</sup> whereas poor outcome is strongly linked to severity of disease at presentation<sup>55</sup> and also male sex.<sup>57</sup>

## CLINICAL PICTURE

In 80% of patients, the uveitis is insidious, asymptomatic, and may result in blindness if left untreated.<sup>56</sup> During exacerbations, patients may manifest discomfort and redness. This picture is most frequently bilateral, with either simultaneous presentation or with second eye involvement generally occurring after a few months and rarely after 1 year.<sup>60</sup>

The typical presentation is bilateral, nongranulomatous iridocyclitis with small keratic precipitates in the inferior half of the cornea and mild-to-severe anterior chamber flare and cells and anterior vitreous cells. Granulomatous presentation has been reported, but it is important here to exclude other diseases, especially sarcoidosis.<sup>61</sup>

An acute anterior uveitis may be seen in enthesitis-related arthritis and tends to occur in older HLA-B27-positive boys, with pain, redness, and photophobia. These patients may develop spondyloarthropathy in adult life, with recurrent acute anterior uveitis.<sup>46</sup>

Most cases of uveitis are diagnosed within 4 years of the onset of arthritis<sup>60,62</sup> but may occur sooner, especially in those with extended oligoarthritis, who tend to fall ill quite early on.<sup>63</sup> Some individuals may develop uveitis after the age of 16, and this could be either asymptomatic or symptomatic. One study found that many patients with uveitis continue to show disease activity in adult life and that this was usually associated with activity of the joint disease.<sup>63</sup> The same study found that patients with acute symptomatic uveitis had their first attack of uveitis later in life and that they were all HLA-B27-positive and ANA-negative.

A study of 358 children with oligoarthritis and rheumatoid factor-negative polyarthritis showed that an elevated ESR appeared to be a predictor for the occurrence of uveitis in patients with JIA, and the authors propose its use as a biomarker in daily practice.<sup>64</sup>

## COMPLICATIONS AND PROGNOSIS

The chronic nature of the disease, with periods of exacerbation, will determine the complications associated with this condition. Most of the damage involves the anterior segment of the eye, but permanent alterations may also affect the posterior segment.<sup>65</sup> The most common complications include: band keratopathy, posterior synechiae, cataract, glaucoma, cystoid macular edema, and cyclitic membrane with hypotony.<sup>46</sup>

Another factor associated with complications is a high flare, with a reading of less than 20 photon units per second (pms) at the time of initial assessment being associated with significantly lower prevalence of complications.<sup>66</sup>

Cataract, usually posterior subcapsular, is common, with a cumulative incidence of 20.5%,<sup>52</sup> and results from chronic inflammation and chronic use of corticosteroid therapy. Anterior subcapsular opacities will also appear in places where posterior synechiae develop. The reported prevalence is variable but approaches 50%.<sup>67,68</sup>

Secondary glaucoma can be sight threatening. In the majority of affected eyes the intraocular pressure increases shortly after control of inflammation is achieved, suggesting recovery of ciliary body function and chronic damage to trabecular meshwork from chronic inflammation, peripheral anterior synechiae, and corticosteroids.<sup>69</sup> The cumulative incidence of glaucoma has been found to be 18.9%,<sup>52</sup> with a reported range of 14%–42%.<sup>67,70,71</sup>

Band keratopathy occurs in long-standing inflammation and tends to affect the interpalpebral area, with a cumulative incidence of 15.7%.<sup>52</sup> Other less frequent complications are vitritis, cystoid macular edema, disc edema, and disc neovascularization.<sup>72</sup> In severe cases, retinal detachment, hypotony, and phthisis bulbi may occur, indicating poor prognosis.<sup>46</sup>

Hypotony is uncommon and usually reflects severe and mostly poorly controlled uveitis, and this can be reduced by more aggressive immunosuppression and better control of the inflammation.<sup>73</sup>

A higher frequency of complications is associated with severe disease, uveitis onset before arthritis at a young age, and delayed referral to a specialist with consequent delay in therapy.

Recent work on assessment of quality of life in adult patients with JIA has shown that having a history of uveitis has a negative effect on the vision-related quality-of-life scores in adulthood even in the presence of good visual acuity. The same work showed that the general quality of life scores was not different in relation to presence of absence of uveitis but was affected by the use of systemic immunomodulatory treatment.<sup>74</sup>

## MANAGEMENT

Early identification with prompt and aggressive therapy is the cornerstone of prevention of complications and visual loss. The benefit of early aggressive intervention can be demonstrated by a reduction of the anterior chamber flare readings associated with risk of complications in patients with active uveitis and uveitis duration of less than 1 year.<sup>66</sup> The management should be carried out by an experienced ophthalmologist, often with the help of a pediatric rheumatologist. Even with aggressive, early therapy, long-term visual loss can result.

Local therapy involves the use of high-potency corticosteroid eyedrops, initially at a high frequency, associated with short-acting mydriatic drops, such as tropicamide or cyclopentolate, with the main objective of preventing the formation of posterior synechiae. Long-acting mydriatics such as atropine should be avoided because their use may result in synechiae in a dilated position and because of cycloplegia may induce amblyopia.<sup>75</sup> Other forms of local therapy include topical NSAIDs<sup>75,76</sup> and periocular injections of corticosteroids, mainly in refractory cases. It is important to remember that systemic absorption from both frequent strong topical corticosteroid and periocular corticosteroid injection can be substantial; systemic adverse reactions including Cushing's syndrome may be seen in children.<sup>77,78</sup>

A study on 16 eyes with recalcitrant JIA-related uveitis showed that the use of sustained-release dexamethasone device can result in better control of anterior inflammation and resolution of macular edema. Development of cataract and increase in intraocular pressure remain the most common complications of this approach.<sup>79</sup>

Some patients will require systemic therapy. Long-term oral corticosteroids are a poor option, and the early introduction of immunosuppressive agents will result in better disease control and will be corticosteroid-sparing. Methotrexate (MTX) can be administered either orally or subcutaneously—especially if patients develop gastric side effects during oral therapy—at a dose of 10–15 mg/m<sup>2</sup> per week (typical dose: 7.5–25 mg/week) and seems

to be quite effective in 70%–80% of patients.<sup>80</sup> Relapses may occur soon after withdrawal of MTX, and a period of inactivity longer than 2 years is necessary to reduce the risk of such events.<sup>81</sup>

Azathioprine has been used with success,<sup>82</sup> and others, including cyclosporine (not very effective as monotherapy) and alkylating agents for the most severe cases, have been used.<sup>82,83</sup>

Mycophenolate mofetil has also demonstrated effectiveness in childhood uveitis, with corticosteroid-sparing success in 88%–92% of patients.<sup>80</sup>

Biological agents offer a new modality of treatment for autoimmune diseases. A recent retrospective study of high-dose infliximab in 17 children with chronic uveitis (10 with JIA uveitis) has shown it to be effective and well tolerated in refractory cases.<sup>84</sup> Adalimumab is currently preferred following a study demonstrating it to be effective in severe JIA/polyarthritis.<sup>85</sup> It is considered the most efficacious TNF- $\alpha$  blocker for childhood uveitis and the preferred biological drug for the treatment of uveitis associated with JIA (23 of 13). Another prospective open-label, noncomparative, multicenter study assessed the safety and efficacy of adalimumab in 39 patients with JIA-associated refractory uveitis. They found a significant difference in the mean immunosuppression load baseline and end of follow-up and a decrease in mean dose of corticosteroids during the same period.<sup>86</sup>

A systematic review of 128 articles published on use of anti-TNF agents in children with autoimmune chronic uveitis showed that despite the fact that no randomized controlled trials are available, there is some evidence that switching to a second anti-TNF agent results in improvement of ocular activity for 75% of the treated children.<sup>87</sup> Tocilizumab (TCZ), an anti-interleukin 6 receptor antibody, appears to represent an option for severe cases that have been refractory to MTX and TNF- $\alpha$  inhibition.<sup>88</sup>

Rituximab has been suggested for use in severe cases that fail to respond to all other options.<sup>89,90</sup> This response is compatible with histopathological findings reporting a heavy infiltration of CD20+ cells.<sup>91</sup> Other alternatives include abatacept, which showed benefit in cases refractory to anti-TNF therapy,<sup>92</sup> and daclizumab, which also showed good response when higher doses were used.<sup>93</sup>

## MANAGEMENT OF COMPLICATIONS

The management of cataract poses a special challenge, especially in younger children. Control of the inflammatory process is essential for a favorable outcome, but young patients need intervention quickly to prevent the development of amblyopia. With good control of inflammation and use of immunosuppressive therapy, favorable outcomes can be achieved with the use of intraocular lenses (IOLs).<sup>94</sup> No difference in complication rate was found between aphakic and pseudophakic children who had maximum control of inflammation for 3 months prior to surgery, but there was significant superiority of visual acuity in the pseudophakic group.<sup>95,96</sup> However, there is some evidence that an intact posterior capsule and anterior vitreous are associated with a higher incidence of cyclitic membrane formation and progression to hypotony and phthisis.<sup>97</sup> For this reason, many authors suggest total removal of the lens either by vitreo-lensectomy or by phacoemulsification (phaco) combined with vitrectomy and without IOL implantation. This approach has shown good outcomes, with visual acuity of 20/40 or better in 75% of the eyes.<sup>98</sup>

Secondary glaucoma is often refractory to medical therapy, with a poor response to topical beta-blockers, sympathomimetics, and carbonic anhydrase inhibitors. Prostaglandin analogues may be used when these options fail. Conventional filtering surgery may be used but will require antimetabolites. Glaucoma implant devices, such as the Molteno implant, seem to be well tolerated and produce good control of intraocular pressure.<sup>99</sup>

Cystoid macular edema initially can be treated with a topical combination of corticosteroid and nonsteroidal drugs, with the option of periocular corticosteroids in case of failure. Systemic therapy including immunosuppression can be used in resistant cases, especially if sight is threatened.<sup>75</sup> Vitrectomy may be helpful in some cases. Symptomatic band keratopathy may be treated by chelating agents or excimer laser.

Intervention in cases of retinal detachment and hypotony is often unsuccessful.

## OUTCOMES

Older studies found that one-third of affected eyes develop visual impairment and one-tenth become blind.<sup>100</sup> Even now, poor visual acuity is found in as many as 20% of the children, and as many as 10% of eyes are blind.<sup>101</sup> In a recent meta-analysis, the adverse visual outcome cumulative incidence was found to be 9.2%, which is lower than some reports.<sup>52</sup> Poor visual outcome is more common in those who have developed uveitis prior to or

TABLE 7.14.1 Frequency of Ophthalmological Visits for Children With Juvenile Idiopathic Arthritis and Without Known Iridocyclitis

Juvenile Idiopathic Arthritis Subtype at Onset	Age at Onset of Arthritis	
	<7 Years <sup>†</sup>	>7 Years <sup>‡</sup>
Pauciarticular (ANA positive)	H <sup>§</sup>	M
Pauciarticular (ANA negative)	M	M
Polyarticular (ANA positive)	H <sup>§</sup>	M
Polyarticular (ANA negative)	M	M
Systemic	L	L

\*High-risk (H) patients should have ophthalmological examinations every 3–4 months. Medium-risk (M) patients should have ophthalmological examinations every 6 months. Low-risk (L) patients should have ophthalmological examinations every 12 months. ANA indicates the antinuclear antibody test.

<sup>†</sup>All patients are considered at low risk 7 years after the onset of their arthritis and should have yearly ophthalmological examinations indefinitely.

<sup>‡</sup>All patients are considered at low risk 4 years after the onset of their arthritis and should have yearly ophthalmological examinations indefinitely.

<sup>§</sup>All high-risk patients are considered at medium risk between 4 and 7 years after the onset of their arthritis.

Adapted from American Academy of Pediatrics Section on Rheumatology and Section on Ophthalmology. Guidelines for ophthalmologic examinations in children with juvenile rheumatoid arthritis. Pediatrics 1993;92:295–6.

at the same time as arthritis.<sup>44</sup> Poor prognosis has not been associated with the presence of a positive ANA.<sup>101</sup>

Eyes with ocular hypertension or secondary glaucoma have close to threefold higher incidence of legal blindness, and this risk can be reduced by early introduction of immunosuppressive therapy.<sup>102</sup>

The Systemic Immunosuppressive Therapy for Eye Diseases (SITE) study assessed the incidence of—and risk factors for—visual acuity loss and ocular complications in patients with JIA-associated uveitis. The study included 327 patients from five tertiary uveitis clinics in the United States. It found that 60% of the patients had at least one ocular complication. Increasing uveitis activity was associated with increased risk of vision loss, and the risk was reduced by the use of immunosuppressive drugs.<sup>103</sup>

### SCREENING

The purpose of screening programs is to identify and closely monitor patients who are considered to be at high risk of developing uveitis and its complications following the diagnosis of arthritis. Several strategies have been used and are usually based on the subtype of arthritis, gender, age at onset of arthritis, and ANA status (Table 7.14.1).<sup>104,105</sup> A recent analysis of risk factors used severity of disease at diagnosis as a surrogate measure of the effectiveness of current screening programs. Because of a lack of improvement in this marker in the recent past, it was suggested that

current screening strategies should be improved, and it was proposed that female patients with JIA should have an eye examination every 2 months for the first 6 months after developing arthritis and that males should have the same frequency of examinations but for a period of 12 months.<sup>59</sup>

Another report suggests that routine eye examinations should continue during early adult life, since some patients first developed asymptomatic uveitis at this age.<sup>63</sup>

An assessment of the outcome of ophthalmological screening for uveitis in a cohort of Swedish children with JIA concluded that almost all children developed uveitis within 4 years following arthritis onset, which reinforced the need for frequent follow-ups during this period. In this study the most important predictor for the development of uveitis was ANA positivity.<sup>106</sup>

# Sarcoidosis

Claude L. Cowan, Jr.

# 7.15

**Definition:** A multisystem inflammatory disorder characterized histologically by the presence of noncaseating granulomas in involved tissues.

## Key Features

- Anterior and posterior uveitis.
- Bilateral hilar lymphadenopathy and/or pulmonary parenchymal disease.

## Associated Features

- Cutaneous lesions.
- Neurological abnormalities, including optic neuropathy.
- Cardiomyopathy.
- Orbital and conjunctival infiltration.
- Arthropathy.

## INTRODUCTION

Sarcoidosis is a chronic multisystem disorder characterized histologically by the accumulation of noncaseating epithelioid granulomas in affected tissues. The wide variability in clinical features and prevalence are felt to reflect the effects of genetic and environmental influences that shape the characteristics of the disease. Its course shows a similar variability, ranging from an asymptomatic self-limiting process to a chronic progressive disorder resulting in severe functional impairment or death. Ocular involvement is common and may precede the clinical manifestations of systemic sarcoid. Corticosteroids remain the mainstay of treatment for both ocular and systemic sarcoidosis, but adjunctive therapy with other immunomodulatory agents may be required in the face of intolerable corticosteroid side effects or progressive disease.

## EPIDEMIOLOGY AND PATHOGENESIS

Sarcoidosis is worldwide in distribution, but its prevalence and clinical manifestations vary widely from one region to another. This variability may reflect differences in study design, case definition, population demographics, the limited use of population-based screening, and seasonal variations in activity. In addition, the asymptomatic and nonspecific nature of many findings may lead to missed opportunities for diagnosis. Nevertheless, true regional and ethnic differences appear to exist.<sup>1-6</sup> The incidence has been highly correlated with race in the United States, where the age-adjusted incidence is more than three times higher among African Americans than among European Americans, with the highest incidence being reported among African-American women.<sup>3,6</sup> A similar predilection for people of African descent has not been confirmed throughout Africa but has been noted in South Africa.<sup>7</sup> Sarcoidosis tends to be a disorder of young and middle-aged adults, but it is also well described in children and in the elderly.

The etiology of sarcoidosis remains elusive, but evidence suggests that it is a genetically determined immune response to some environmental trigger. Bacteria and bacterial DNA fragments have been found in sarcoid granulomas and bronchoalveolar lavage (BAL) fluid, and localized and regional granulomatous responses have been produced following inoculation of sarcoid material into laboratory animals.<sup>8-11</sup> However, experimental exposures have not been followed by the development of a systemic disease

comparable to that seen in humans. Nevertheless, reports of “transmission” of sarcoidosis through organ transplantation and clustering of the disease in families and coworkers suggests that transmissible agents may be contributing factors.<sup>12-14</sup>

The similarity between sarcoidosis and chronic beryllium disease, along with other environmental associations, has stimulated an interest in the relationship between occupational exposures and sarcoid.<sup>15-19</sup> However, recall bias, the inability to establish exposure thresholds, and association with disparate occupational categories make linkage of specific exposures to disease difficult.

The role of genetic factors is supported by the association of several human leukocyte antigen (HLA) haplotypes and ethnicity with disease risk and clinical course.<sup>20-24</sup> In addition, although familial clustering is consistent with an environmental agent, the greater prevalence among certain parent-offspring and sibling pairs suggests that genetic influences are at least as important as environmental ones.<sup>25</sup> It is likely that multiple genotypes exist that, in the presence of one or more environmental triggers, predispose to an immunological response that is recognized phenotypically as sarcoidosis.

## OCULAR MANIFESTATIONS

Ocular involvement is common, having been reported in up to 83% of patients. It may be second only to pulmonary disease as the presenting manifestation of sarcoid.<sup>26-31</sup>

Anterior uveitis is an important cause of sarcoid-related ocular morbidity. It frequently presents early in the disease course and may present a year or more before the diagnosis of systemic sarcoid. It is usually granulomatous in character (Fig. 7.15.1) and may be accompanied by iris and trabecular nodules (Fig. 7.15.2), the latter being frequently associated with ocular hypertension. Although unilateral disease occurs, bilaterality is typical. An insidious onset is not uncommon, and patients may have anterior or posterior synechiae at the time of initial presentation. Acute anterior uveitis is not characteristic, but it is a feature of acute sarcoidosis or Lofgren's syndrome, which features hilar adenopathy, polyarthritides, fever, and erythema nodosum. The course of anterior uveitis can be monophasic,

**Fig. 7.15.1 Chronic Sarcoid Uveitis.** Multiple iris nodules and posterior synechiae.

relapsing, or chronic and may not parallel the severity or activity of the systemic disease.

Other anterior segment and external manifestations include conjunctival granulomas, scleral nodules, a nonspecific conjunctivitis, episcleritis, interstitial keratitis, and band keratopathy. Conjunctival granulomas are often located in the inferior fornix and are generally asymptomatic. When extensive, they can resolve with symblepharon formation. Anterior and posterior scleral nodules can be seen and are variably responsive to corticosteroids but are not typically associated with severe pain or necrosis. Diffuse or multifocal gray infiltrates are seen with sarcoid keratitis and may leave faint superficial opacities with resolution.

Periphlebitis and vitritis are the most common manifestations of posterior-segment sarcoid and often occur together. Periphlebitis frequently involves the midperipheral or peripheral retina, but any venous segment can be involved. When severe, the involved venous segments may demonstrate extensive perivascular exudation that has been likened to candle wax drippings. These periphlebitic foci can take on a hard, smooth texture as they resolve (Fig. 7.15.3). Periphlebitis can be complicated by venous occlusion leading to neovascularization that may simulate the sea fans of sickle retinopathy in the peripheral retina. Retinal arteritis is less commonly reported and has been associated with multifocal arterial ectasias.<sup>32,33</sup>

Vitritis may be generalized with a diffuse loss of media clarity or characterized by discrete gray-white opacities that can be scattered throughout the vitreous or primarily involve the inferior vitreous. These “snowball”

opacities can occur singly, in clusters, or in a linear array or strand, like a “string of pearls.” Veil-like condensations often cause bothersome symptoms, but in the absence of severe media opacification or macular edema, the vision usually remains good. Sarcoid retinitis is relatively uncommon and can be difficult to distinguish from other causes of retinal inflammation such as viral retinitis or toxoplasmosis.

Choroidal lesions vary considerably in their appearance, ranging from isolated tumefactions to multifocal granulomas simulating multifocal choroiditis (Fig. 7.15.4). Dalen–Fuchs’-like nodules may slowly increase in number over time and evolve into focal atrophic spots. On fluorescein angiography, the lesions may be nonfluorescent, hypofluorescent, show early blocking with late staining, or hyperfluorescent throughout. If the eye is otherwise uninvolved, patients may be entirely asymptomatic. Vision loss can be associated with serous detachment of the macula, pigment epithelial dropout, or subretinal neovascularization.

Sarcoid involves the optic nerve infrequently but can be the presenting feature of the disease.<sup>34</sup> Clinical manifestations include nodular infiltration, swelling associated with adjacent retinitis, papillitis, juxtapapillary granulomas, or papilledema associated with increased intracranial pressure (Fig. 7.15.5). Retrobulbar or chiasmal lesions can present with progressive vision loss in the face of a normal-appearing nerve until advanced disease leads to optic atrophy. The combination of optic neuropathy and intermediate uveitis can cause confusion with multiple sclerosis.

Dacryoadenopathy is part of the spectrum of orbital sarcoid and is its most common expression.<sup>35</sup> Patients often present with asymptomatic

swelling that is most pronounced over the lateral aspect of the upper lid or with a palpable mass in the anterior orbit. One or both eyes may be involved, and adenopathy can occur in the absence of other evidence of sarcoid. Severe infiltration can lead to proptosis and may be associated with keratoconjunctivitis sicca. Other orbital manifestations include isolated orbital granulomas, extraocular muscle lesions, and optic nerve sheath infiltration.

Although any ocular structure may be involved, the individual signs of ocular sarcoid are nonspecific, and evidence of sarcoid in other organs and/or biopsy are frequently required to establish the diagnosis. However, in 1976, Iwata and colleagues identified six clinical findings that were felt to be most suggestive of sarcoidosis.<sup>27</sup> These included:

- Nodular infiltration of the angle.
- Nodular iridocyclitis and large mutton-fat keratic precipitates.
- Chorioretinal granulomas and placoid lesions.
- Vitreous string of pearls and snowball opacities.
- Retinal perivasculitis.
- Candlewax drippings and yellow “waxy” spots.

Their predictive value increased when multiple lesions were present and ranged from 75%–100% when three or more signs were present. Nodular trabeculitis was the single most suggestive finding. Subsequent reports have identified similar suggestive signs, and Herbot et al. added tent-like peripheral anterior synechiae, optic disc granulomas, retinal macroaneurysms, and bilaterality as signs compatible with a diagnosis of sarcoidosis.<sup>36–40</sup>

Conversely, findings such as hyphema, angle neovascularization, epithelial keratitis, hypopyon, peripheral ulcerative keratitis, acute orbital inflammation, and iris atrophy are unusual in sarcoid and should suggest other diagnoses.

## DIAGNOSIS

There is no specific diagnostic test for sarcoid. Diagnosis is based on the presence of a compatible clinical picture, supportive laboratory and radiological findings, a confirmatory biopsy, and the exclusion of other likely causes of granulomatous inflammation. Bilateral hilar adenopathy (Fig. 7.15.6) with or without parenchymal infiltrates is the radiological hallmark of sarcoid; in the absence of symptoms, abnormal findings on physical exam, or anemia, other diagnoses are unlikely.<sup>41</sup> The greater sensitivity of

**Fig. 7.15.6 Bilateral Hilar Adenopathy in a Patient Without Pulmonary Symptoms.** Note the symmetry of the hilar node enlargement.

chest computed tomography (CT) allows detection of parenchymal abnormalities that are invisible on chest X-ray and permits visualization of disease along the bronchovascular bundles as well as subpleural disease, locations that are suggestive of sarcoid.<sup>42</sup> Although pleural effusion has been variably described, it and asymmetric or unilateral adenopathy should prompt consideration of other disorders. One or more skin lesions occur in approximately 25% of patients, but they frequently mimic other dermatological lesions.<sup>26,43</sup> However, when associated with bilateral hilar adenopathy, lupus pernio and erythema nodosum are sufficiently characteristic that a presumptive diagnosis of sarcoid should be considered. Typical skin lesions are neither painful nor pruritic, and genital lesions should prompt other considerations. Other nonocular extrapulmonary manifestations are less reliable predictors of sarcoid, but in the appropriate clinical setting, nontender peripheral lymph adenopathy, Bell's palsy, and early childhood arthritis should raise the index of suspicion for sarcoid.

Serum angiotensin-converting enzyme (ACE) is elevated in approximately 60% of patients and correlates with the degree of active pulmonary disease.<sup>44</sup> However, diabetes, alcoholic liver disease, hyperthyroidism, leprosy, chronic renal disease, and tuberculosis can also elevate serum ACE, and levels are normally higher in children.<sup>45</sup> Conversely, a normal ACE does not rule out sarcoid as levels may be lower in patients on ACE inhibitors.<sup>46</sup> In addition, genetic polymorphism can modify ACE expression, thus affecting the interpretation of enzyme levels.<sup>47</sup> Although elevated ACE levels have moderate sensitivity and good specificity, in isolation they are neither specific nor sensitive for the diagnosis of sarcoidosis.<sup>48</sup> Interleukin-2 receptor has been shown to be a marker for pulmonary and ocular sarcoid and may be more sensitive than ACE.<sup>49,50</sup> However, it is not specific for sarcoid and may be elevated in other disorders.<sup>51</sup> Serum lysozyme may also be elevated in sarcoidosis and other inflammatory conditions and can be particularly useful in young patients where ACE levels are normally elevated. Other tests such as serum and urine calcium, immunoglobulin electrophoresis, and liver function tests are less useful as isolated investigations, but when used selectively can support the diagnosis. Nevertheless, with 90% or more of patients having thoracic disease, chest imaging may be the single most useful investigation.

Impaired recruitment of helper cells in the skin leads to relative anergy to recall antigens in sarcoidosis, and anergy panels can provide useful information when patients are known to have been previously positive to the test antigen. The association of anergy with sarcoidosis is sufficiently strong that a negative tuberculin skin test in an individual previously exposed to or living in areas endemic for tuberculosis suggests sarcoidosis associated anergy. Conversely, a positive tuberculin skin test in a patient suspected of having sarcoid should prompt further workup for tuberculosis.<sup>52</sup>

Gallium-67 scanning is used relatively infrequently to diagnose sarcoid, but in combination with serum ACE assays it can provide good sensitivity and specificity.<sup>53</sup> Bilateral hilar and right para tracheal uptake (lambda sign) combined with increased uptake in the parotids and orbits (panda sign) is highly suggestive of sarcoid even in the absence of a confirmatory biopsy.<sup>54,55</sup>

Tissue or fluid sampling is usually sought to provide histological confirmation of sarcoid. Bronchoscopy provides ready access to pulmonary tissue and samples can be obtained by endo- or transbronchial biopsy (TBB). TBB is most likely to be positive in patients with active pulmonary disease visible on chest X-ray, and the yield is increased when combined with endobronchial sampling, especially if done using ultrasound-guided endobronchial needle aspiration.<sup>56</sup> Analysis of bronchoalveolar lavage fluid can provide supporting evidence of disease as a lymphocytosis associated with an increased T lymphocyte CD4/CD8 ratio is consistent with the alveolitis of sarcoidosis.<sup>57</sup> Open lung biopsy and mediastinoscopy are higher risk alternatives when bronchoscopy fails to yield suitable samples. Conjunctiva, lacrimal gland, peripheral lymph nodes, skin, nasal mucosa, and minor salivary glands are attractive alternate biopsy sites, as they are easily accessible. Conjunctival biopsies are most likely to be positive when granulomas are visible and multiple samples are taken from both eyes. Intraocular fluid sampling can also demonstrate cytological features consistent with sarcoid in patients with intraocular disease.<sup>58,59</sup>

## DIFFERENTIAL DIAGNOSIS

The varied clinical presentations of ocular sarcoid and the features it shares with other diseases offer many opportunities for misdiagnosis.

Iris nodules are features of granulomatous uveitis and can be seen with tuberculosis, syphilis, leprosy, herpetic uveitis, toxoplasmosis, and Vogt–Kayanagi–Harada syndrome. Isolated or multifocal nodular iris lesions are

also seen with primary iris neoplasms, metastatic carcinoma, leukemic infiltrates, and seeding from retinoblastoma. Intermediate uveitis can be associated with Lyme disease, inflammatory bowel disease, tuberculosis, and multiple sclerosis, or it may occur on an idiopathic basis known as pars planitis. Choroiditis and choroidal infiltrates are manifestations of multiple disorders that may share some feature with sarcoid. These include infectious diseases such as histoplasmosis, tuberculosis, syphilis, toxoplasmosis, and pneumocystis choroidopathy and a variety of noninfectious disorders, including acute posterior multifocal placoid pigment epitheliopathy, birdshot choroidopathy, multifocal choroiditis with pan uveitis, Vogt-Koyanagi-Harada disease, sympathetic ophthalmia, and lymphoma. In addition, solitary lesions may suggest central serous choroidopathy, amelanotic melanoma, or a choroidal metastasis. Differentiating these from sarcoid may be difficult based on the fundus picture alone; the history and clinical course or associated systemic signs may provide crucial clues to the correct diagnosis.

Sarcoid-associated dacryoadenopathy and parotitis can mimic tuberculosis, Hodgkin's disease, lymphoma, and brucellosis. In addition, isolated lacrimal gland enlargement may be a feature of thyroid disease, orbital pseudotumor, primary lacrimal gland tumors, and Sjögren's syndrome. Peripheral retinal neovascularization occurs relatively infrequently in sarcoid, and more common causes such as diabetic retinopathy and venous occlusive disease should be ruled out. Proliferative sickle retinopathy must also be considered in patients genetically predisposed to sickling disorders.

Infiltrative disease of the optic nerve, other inflammatory optic neuropathies, ischemic optic neuropathy, optic nerve sheath meningioma, and disc edema from any cause all have features that can be mimicked by sarcoidosis. Avoidance of misdiagnosis can be difficult when other signs of sarcoid are absent, and delays in diagnosis are not uncommon.

## SYSTEMIC ASSOCIATIONS

Sarcoidosis is a multisystem disorder that can involve virtually any organ. It is accompanied by abnormalities in cell-mediated and humoral immunity that lead to impaired responsiveness to recall antigens, depressed circulating T cell levels, elevated globulin levels, and nonspecific elevation of antibody titers.

It involves the lungs and/or thoracic nodes in 90% of patients and is staged based on the radiographic findings (Scadding scale).<sup>60</sup> These stages do not represent the natural history of the disease but may be useful in predicting prognosis with pulmonary disease.

- Stage 0: No abnormalities on chest X-ray; parenchymal abnormalities may be detected on CT.
- Stage I: Bilateral hilar and mediastinal adenopathy; the most common stage at presentation.
- Stage II: Hilar adenopathy plus parenchymal involvement (nodular and reticular opacities).
- Stage III: Parenchymal disease alone.
- Stage IV: Advanced disease with fibrosis.

Sarcoid is often insidious in onset, and many patients are initially asymptomatic. Dyspnea, cough, and chest pain are common presenting complaints and may progress slowly. Airway obstruction is the most common functional abnormality consistent with the high prevalence of endobronchial disease found on bronchoscopy, and it may be associated with intractable coughing or wheezing.<sup>61</sup> Restrictive lung disease, impaired diffusing capacity, and pulmonary arterial hypertension are variably present, and pleural thickening can be demonstrated with CT.

Otorhinolaryngological involvement occurs in 10%–15% of patients and can be overlooked as the symptoms may suggest a nonspecific rhinitis.<sup>62</sup> Nasal mucosal disease is associated with mucosal friability causing crusting and bleeding as well as submucosal nodules. Xerostomia from salivary gland involvement, vestibular symptoms, and hearing loss may also occur. Rarely will lacrimal outflow obstruction lead to epiphora. Complaints of nasal stuffiness or congestion, postnasal drip, or recurrent sinusitis should prompt an examination of the nasal mucosa for lesions on the inferior turbinates or septum.

Cutaneous manifestations are common and include nodules, plaques, psoriasiform lesions, papules, ulcerations, and erythema nodosum.<sup>26,43</sup> Sarcoid may have a predilection for sites of recurrent trauma or old scars, but lesions can occur anywhere. Subcutaneous nodules are uncommon but are notable for their association with coexisting autoimmune disorders. Lupus pernio, plaque-like lesions that involve the face, can be disfiguring and may be of prognostic value because of their association with

**Fig. 7.15.7 Multiple Cutaneous Lesions Involving the Lids.** Papules, a few umbilicated lesions, and small plaques are evident in this patient.

chronic disease. Eyelid lesions mirror those seen elsewhere and should be considered part of the cutaneous disease (Fig. 7.15.7).

Peripheral lymphadenopathy occurs in up to 30% of patients and most often involves the cervical, axillary, epitrochlear, and inguinal nodes.<sup>26</sup> It is a nonspecific finding, but the nodes provide useful biopsy sites. Tender adenopathy is atypical for sarcoid and should suggest an alternative diagnosis.

Cardiac involvement is clinically apparent in approximately 5% of patients, but it has been reported in as high as 76% in autopsy series.<sup>63</sup> Conduction defects as well as ventricular and supraventricular arrhythmias may occur, but there are no specific clinical or electrocardiographic findings. The association of heart block with myocardial sarcoid requires caution when using beta-blockers in patients who have glaucoma, and a history of palpitations or other cardiac symptoms should prompt referral to a cardiologist.

Neurosarcoid is clinically evident in 5%–10% of patients and may precede other manifestations of the disease.<sup>64,65</sup> Any part of the nervous system can be involved and when isolated, the nonspecificity of symptoms may delay diagnosis. It has a predilection for the basal leptomeninges, and cranial nerve involvement is a common feature, especially the second, seventh, and eighth nerves. Hypothalamic and pituitary involvement can cause significant endocrine abnormalities and diffuse hemispheric disease may lead to seizures. Localized central nervous system (CNS) infiltration can simulate intracranial tumors and may cause hemianopic or quadrantanopic field defects. Spinal tract lesions are unusual but can cause paralysis. Peripheral neuropathy and myopathy occur less frequently than CNS disease and can lead to muscle weakness, paresthesias, and abnormal deep tendon reflexes. Psychiatric symptoms are rare and when present in patients taking systemic corticosteroids, an adverse medication effect should be considered. Notably, ocular sarcoid is reported to occur more frequently with neurosarcoid than other systemic manifestations.<sup>66</sup>

Hepatic and splenic involvement cause symptomatic disease in a minority of patients, but abnormal liver function tests are not uncommon, and hypodense lesions can be seen on CT and magnetic resonance imaging (MRI). Hypercalcemia and/or hypercalcuria occur secondary to increased production of 1,25 dihydroxyvitamin D by activated macrophages and increase the risk for nephrocalcinosis and nephrolithiasis. Arthralgias have been reported in 25%–38% of patients, some of whom demonstrate phalangeal bone cysts on imaging.

Pediatric sarcoid has two distinct clinical presentations.<sup>67</sup> Early onset sarcoid occurs in children less than 4 years of age and is characterized by the triad of granulomatous dermatitis, polyarthritis, and uveitis. It is believed to be the sporadic form of the disorder known as Blau syndrome.<sup>68</sup> Older children and adolescents typically present with features similar to those in adults and often have pulmonary involvement and lymphadenopathy. Anterior uveitis, when present, is more likely to be nongranulomatous.<sup>69</sup>

## PATHOLOGY

Sarcoid lesions demonstrate granulomas with central nodules of epithelioid cells surrounded by a mantle of lymphocytes and other mononuclear cells. Although mild central necrosis may be seen, caseation is not

a feature of sarcoidosis. Fibrosis may be associated with maturation of sarcoid granulomas.

## TREATMENT

No known cure exists for sarcoidosis, and recurrences are not unusual even after prolonged periods of quiescence. Treatment is primarily intended to reduce symptoms, lessen disability during periods of activity, and minimize the sequelae of inflammation. Corticosteroids remain the mainstay of treatment for ocular and extraocular sarcoid.

Chronic or recurrent anterior uveitis may require more aggressive therapy than would be suggested by the level of clinical inflammation, and progressive anterior and posterior synechiae can occur in patients with frequent episodes of “silent” reactivation. The latter group of patients may be best served by long-term low-dose maintenance therapy, even in the absence of clinically active disease. Conjunctival follicles often resolve spontaneously, but treatment may be indicated for extensive follicle formation as they can resolve with symblepharon formation. Dacryoadenopathy that is associated with dry eye or is cosmetically bothersome may respond well to systemic corticosteroids.

Posterior uveitis is managed primarily with periocular or systemic corticosteroids. Intravitreal administration is a useful alternative for patients with intolerance to systemic treatment, recalcitrant inflammation, or cystoid macular edema. In the absence of complications, small foci of peripheral periphlebitis or mild vitritis may not require treatment as they can wax and wane without progression. Treatment is variably effective in clearing choroidal infiltrates, but it can be very effective for accompanying serous retinal detachments. The association of subretinal neovascularization with choroidal inflammation suggests that a trial of empiric therapy should be considered for macular lesions even in the absence of symptoms or serous elevation of the retina. Optic nerve involvement can be resistant to even high doses of oral corticosteroids, and “pulsed” intravenous methylprednisolone may be required to achieve a response. Occasionally, retrobulbar injection is useful for patients with optic nerve disease who are intolerant of systemic corticosteroids. Cytotoxic and other immunomodulatory agents are useful adjuncts to corticosteroid therapy for refractory anterior or posterior segment disease and as part of a corticosteroid-sparing strategy.

Indications for the treatment of systemic sarcoid include intolerable symptoms, organ dysfunction, and biochemical or radiological deterioration. Treatment of asymptomatic patients is not usually indicated as it may offer little long-term benefit and can expose the patient to unnecessary side effects. In spite of the paucity of controlled clinical trials on their use, oral corticosteroids are the first line of therapy for most patients due to their relatively rapid onset of action and effectiveness, at least over the short term.<sup>70-72</sup> Inhaled corticosteroids have a limited role in the management of pulmonary sarcoid, and current evidence suggests that they provide no consistent benefit to lung function although they may provide symptomatic relief for patients with persistent cough or wheezing. Other immunomodulatory agents, including methotrexate, azathioprine, mycophenolate mofetil, pentoxifylline, cyclophosphamide, and chlorambucil have been used for refractory disease or to prevent unacceptable corticosteroid-related complications.<sup>73,74</sup> In addition, chloroquine and hydroxychloroquine has been used successfully for cutaneous sarcoid and hypercalcemia, and thalidomide may improve symptoms in early onset childhood sarcoidosis.<sup>75,76</sup>

Infliximab and etanercept have been used with varying success with ocular and systemic disease, but etanercept appears to be less consistently effective and is not recommended for ocular disease.<sup>77-79</sup> Adalimumab may be a useful alternative to infliximab for patients intolerant of the latter drug.<sup>80</sup>

## COURSE AND OUTCOME

The overall prognosis for systemic and ocular sarcoid is good, and most patients recover without significant functional impairment.<sup>81-83</sup> Chronicity increases the risk of complications as does delay in receiving appropriate therapy. Systemic features associated with chronicity or poorer outcomes include diffuse central nervous system disease, lupus pernio, nephrocalcinosis, late stage pulmonary disease, bone abnormalities, hepatosplenomegaly, and cardiac involvement. Clinical depression may occur in more than 50% of patients and even stable patients can have significant reductions in measures of health-related quality of life.<sup>84</sup> Black patients have been reported to be more likely to have symptomatic disease and ocular involvement as well as higher rates of severe complications. However, a systematic review of the literature failed to demonstrate a relationship between ethnicity and sarcoid mortality.<sup>85</sup> Posterior uveitis, cystoid macular edema, secondary glaucoma, and optic nerve involvement are associated with poorer visual outcomes and represent difficult therapeutic challenges.<sup>86-88</sup>

# Behçet's Disease

Annabelle A. Okada

# 7.16

**Definition:** A multisystem vasculitis of unknown cause primarily involving the eyes, the mucosal surfaces, and the skin.

## Key Features

- Recurrent anterior and posterior uveitis.
- Recurrent oral ulcers (aphthae).
- Genital ulcers.
- Skin lesions such as erythema nodosum.

## Associated Features

- Arthritis of large joints.
- Epididymitis.
- Intestinal ulcers.
- Vascular lesions such as thrombophlebitis, arterial occlusions, and aneurysms.
- Central nervous system or cranial nerve involvement.

## INTRODUCTION

Behçet's disease is named after the Turkish dermatologist Hulusi Behçet, who described in 1937 the constellation of recurrent oral ulcers, genital ulcers, and uveitis in three patients.<sup>1</sup> Similar cases had been reported earlier by Shigeta in 1924, Adamantiades in 1931, and Whitwell in 1934.<sup>2</sup> Inflammatory manifestations may also occur in other organ systems, including the skin, the joints, the gastrointestinal tract, and the central nervous system.

## EPIDEMIOLOGY AND PATHOGENESIS

Although Behçet's disease occurs worldwide, it is a particularly common cause of uveitis in countries that line the ancient Silk Road, including Italy, Turkey, Greece, Israel, Saudi Arabia, Iran, China, Korea, and Japan. The age of onset of uveitis is usually in the third to fourth decades of life, with men being more commonly affected than women.<sup>3,4</sup> The uveitis of Behçet's disease is believed to be most severe in young men between 15 and 25 years of age.<sup>3</sup>

The pathogenesis of Behçet's disease remains obscure. The disease has long been associated with the HLA-B51 allele; in Japan, 55% of patients with Behçet's disease are positive for HLA-B51 as opposed to only 10%–15% of the general population.<sup>5</sup> It has been suggested that exposure to various microbial antigens may trigger cross-reactive autoimmune responses in genetically susceptible individuals, leading to the onset of Behçet's disease.

## OCULAR MANIFESTATIONS

Ocular involvement is seen in about 70% of patients with Behçet's disease.<sup>6</sup> In most cases, the onset of uveitis follows the onset of recurrent oral ulcers after 3–4 years, although ocular disease is the initial manifestation in about 20% of cases. Initial ocular involvement may be unilateral but progresses to bilateral disease in at least two-thirds of cases.

Patients with Behçet's disease often present to the ophthalmologist with decreased vision due to anterior chamber inflammation with or without hypopyon (Fig. 7.16.1). Pain, redness, and/or photophobia may be present. The hypopyon typically shifts with change in head position, and a very small hypopyon may be discovered only on gonioscopic examination. There is usually little iris synechia formation initially, although this can

**Fig. 7.16.1 Conjunctival Injection, Hypopyon, and Posterior Synechia.** The patient, who has Behçet's disease, is having an acute inflammatory attack.

**Fig. 7.16.2 Acute Retinal Vasculitis With Retinal Hemorrhages and Cotton-Wool Spots.** Neovascularization at the optic disc is also present.

subsequently develop after repeated bouts of anterior segment inflammation. The intraocular pressure is often normal or low. Mild vitreous cells or mild-to-moderate vitreous opacification commonly occurs. Fundus examination may reveal scattered yellow–white retinal infiltrates, retinal hemorrhages, vascular engorgement, and/or disc hyperemia. However, the fundus may also appear entirely normal during an episode of anterior segment inflammation. Bouts of posterior segment inflammation can also occur in the absence of any anterior chamber cells.

Typically, the clinical course is one of acute exacerbations (“attacks”) and remissions over a background of chronic inflammation. Long-term complications in the anterior segment include iris neovascularization, glaucoma, and cataract. In the posterior segment, retinal vascular sheathing or occlusion, retinal or disc neovascularization (Fig. 7.16.2), vitreous

**Fig. 7.16.3 The Fundus of a Patient Who Has End-Stage Ocular Behçet's Disease.** Note the severe retinal atrophy, vascular attenuation with sheathing, and optic atrophy.

**Fig. 7.16.4 Fluorescein Angiogram of a Patient With Behçet's Disease.** Typical findings include widespread ("fern-like") leakage from the capillary tree and secondary vessels.

hemorrhage, progressive vitreous opacification, and optic atrophy (Fig. 7.16.3) may ensue.

## DIAGNOSIS

The diagnosis of Behçet's disease is based on the constellation of systemic and ocular clinical findings rather than on specific laboratory results. However, some tests are useful adjuncts in the evaluation of patients. Fundus fluorescein angiography may show marked focal or diffuse retinal vascular leakage, occlusion of retinal vessels, and/or optic disc hyperfluorescence. During presumably quiescent periods, in the absence of obvious inflammation in the fundus, dilatation of retinal capillaries with dye leakage is commonly observed (Fig. 7.16.4). Fluorescein angiography may also confirm cystoid macular edema and/or macular ischemia.

During episodes of acute inflammation, patients may have a high erythrocyte sedimentation rate, elevated C-reactive protein, or increased peripheral leukocytes. HLA typing may be helpful depending on the patient population.

There are two widely used diagnostic criteria for Behçet's disease. The first was initially proposed in 1972 by the Behçet's Disease Research

**TABLE 7.16.1 International Study Group Criteria for the Diagnosis of Behçet's Disease**

Finding	Definition
Recurrent oral ulceration	Minor aphthous, major aphthous, or herpetiform ulcers observed by the physician or patient that have recurred at least three times over a 12-month period
<i>Plus at least two of the following criteria:</i>	
Recurrent genital ulceration	Aphthous ulceration or scarring observed by physician or patient
Eye lesions	Anterior uveitis, posterior uveitis, or cells in vitreous on slit-lamp examination or retinal vasculitis detected by an ophthalmologist
Skin lesions	Erythema nodosum observed by physician or patient, pseudofolliculitis, or papulopustular lesions or acneiform nodules observed by physician in postadolescent patients not on corticosteroid treatment
Positive pathergy test	Interpreted by the physician at 24–48 hours
<sup>a</sup> Findings applicable only in absence of other clinical explanations.	

Committee of the Japanese Ministry of Health and Welfare,<sup>7</sup> and a second diagnostic criteria was created in 1990 by the International Study Group for Behçet's Disease (Table 7.16.1).<sup>8</sup> Using the international criteria, the diagnosis of Behçet's disease requires the presence of recurrent oral ulceration plus at least two other findings among recurrent genital ulceration, uveitis, skin lesions, and positive pathergy test (skin prick) result.

## DIFFERENTIAL DIAGNOSIS

The most common diseases mistaken for Behçet's disease with hypopyon formation are HLA-B27-associated acute anterior uveitis and infectious endophthalmitis. Diseases often mistaken for Behçet's disease with posterior segment inflammation include sarcoidosis, tuberculosis, toxoplasmosis, and syphilis. Behçet's disease with panuveitis may look like acute retinal necrosis in the early stages. Numerous other noninfectious and infectious disorders can mimic the ocular findings of Behçet's disease. Thus careful questioning of the patient for systemic signs or symptoms is crucial to making a diagnosis.

## SYSTEMIC ASSOCIATIONS

The major systemic associations are as outlined (see Table 7.16.1). Recurrent ulcers of the oral mucosa are the most common finding, occurring in up to 97.7% of patients,<sup>6</sup> and are usually the initial symptom in Behçet's disease. These lesions may appear anywhere in the mouth, including the lips, buccal mucosa, gingiva, tongue, hard palate, uvula, and oral pharynx. They tend to be painful but heal within 10 days, usually without scarring unless the lesion is particularly large. Skin and genital manifestations have been reported to occur in 90.4% and 79.8% of patients, respectively.<sup>6</sup> Skin manifestations include erythema nodosum, subcutaneous thrombophlebitis, acneiform lesions, and follicular rash. Of these, erythema nodosum occurs the most frequently and is characterized by a slightly raised red nodule with subcutaneous induration and tenderness. These lesions are usually found on the anterior surfaces of the legs, but they may also occur on the face, arms, and buttocks. They tend to involute in 10–14 days without scarring, although some hyperpigmentation may remain.<sup>2</sup> A history of pustular inflammation after accidental skin injury is usually included as skin involvement in Behçet's disease, and such cutaneous hypersensitivity forms the basis of the pathergy test. Genital ulcers may have deeper tissue involvement in comparison to oral ulcers, are generally painful, and often leave scars after healing. The lesions usually occur on the scrotum or vulva but may also be found on the penis and the perianal and vaginal mucosa.

Other manifestations include arthritis, intestinal ulcers, central nervous system disease, and epididymitis. Although rare, myocarditis, various cardiac vascular lesions, pulmonary hypertension, and renal involvement have also been reported in association with Behçet's disease. The most debilitating manifestation by far is central nervous system involvement, which can include both motor and sensory systems and may affect up to 10% of patients.<sup>2</sup> Signs and symptoms include headache, meningismus, nystagmus, tremor, ataxia, speech disturbances, memory impairment, behavioral changes, and dementia.

**Fig. 7.16.5 Behçet's Disease.** Heavy inflammatory cell infiltration around a retinal vessel (hematoxylin-eosin).

## PATHOLOGY

A characteristic feature is a necrotizing, leukocytoclastic, obliterative vasculitis affecting arteries and veins of all sizes. The vasculitic changes seen in the eyes are similar to those observed in other organs.

During acute inflammation, the iris, ciliary body, and choroid show diffuse infiltration with neutrophils. In the retina, there is severe vasculitis with marked infiltration of leukocytes in and around blood vessels (Fig. 7.16.5). During the chronic phase, a lymphocytic and plasma cell infiltration occurs. Retinal vessels develop thickened basement membranes with swollen endothelial cells that can lead to thrombus formation and vascular obliteration. In late stages, there is neovascularization of the iris and retina, formation of cyclitic membranes, and sometimes hypotony and phthisis bulbi. The phthisical globe may reveal a disrupted lens capsule with histological features of phacocanaphylaxis.<sup>9</sup>

## TREATMENT

The short-term goal of therapy for ocular involvement in Behçet's disease is to suppress active inflammation. The long-term goals are to reduce the frequency and severity of recurrences, minimize involvement of the retina and the optic nerve, and avoid complications such as cataract, synechia formation, and glaucoma. Treatment must be started early to be effective. Drug selection should be determined on the basis of the clinical history, location of intraocular inflammation, and the severity of inflammation. As this disease involves other organ systems, a multidisciplinary approach is necessary.<sup>10</sup>

### Corticosteroids

Corticosteroids are effective in the treatment of acute inflammation in Behçet's disease via their potent suppressive effects on the immune system, including neutrophil and macrophage migration and lymphocyte activity. However, they may have limited efficacy in decreasing the frequency of recurrences and preserving visual function.<sup>10–12</sup> Topical corticosteroids are used for anterior segment inflammation, whereas periocular injections (e.g., 20–40 mg triamcinolone acetonide) and/or systemic corticosteroids (e.g., starting dose of 30–80 mg/day prednisolone) are used for posterior segment inflammation. With systemic administration, the corticosteroid dose needs to be tapered slowly, often over years and in combination with a second corticosteroid-sparing agent such as cyclosporine, in order to avoid a rebound effect. The major side effects are hypertension, diabetes mellitus, electrolyte abnormalities, osteoporosis, and reduced resistance to infections. Because of the frequency and severity of side effects of systemic corticosteroid treatment, it is unlikely that patients can remain on this therapy for a prolonged period. Other agents, whether given in combination with low-dose corticosteroids or not, should be considered for long-term treatment in severe cases of uveitis.

## Immunophilin Ligands

Cyclosporine and tacrolimus (FK506) bind to cytoplasmic receptors termed immunophilins in T cells, thereby selectively inhibiting T-cell activity. A Japanese study showed that cyclosporine at a dose of 5 mg/kg/day was effective in decreasing the frequency of ocular inflammatory attacks in 70% of Behçet's patients who had refractory disease.<sup>13</sup> Starting doses of 3–5 mg/kg/day for cyclosporine and 0.05–0.20 mg/kg/day for tacrolimus are commonly used, depending on the severity of disease and whether other agents are being used in combination.<sup>10</sup> Major side effects of the immunophilin ligands are renal dysfunction, neurological abnormalities, gastrointestinal upset, and hirsutism for cyclosporine.

## Cytotoxic Agents

Both antimetabolites (e.g., azathioprine, methotrexate) and alkylating agents (e.g., cyclophosphamide, chlorambucil) have been used in refractory cases of ocular Behçet's disease, particularly before the widespread use of cyclosporine. One masked trial showed that azathioprine, with or without concomitant corticosteroids, was better than placebo in controlling disease.<sup>14</sup> Triple-drug therapy using corticosteroids, cyclosporine, and azathioprine has also been reported to successfully induce remission in some patients.<sup>15</sup> The side effects of cytotoxic drugs may be serious and include bone marrow suppression, hepatotoxicity, secondary malignancies, and decreased fertility.

## Biological Agents

Interferon- $\alpha$  (IFN- $\alpha$ ), infliximab, and adalimumab have shown efficacy for ocular Behçet's disease.<sup>16–25</sup> IFN- $\alpha$  achieved drug-free remission in roughly one-half of patients after discontinuation of the IFN- $\alpha$ , although the adverse effect of flu-like symptoms occurred in 100% of patients during the first weeks of therapy.<sup>17</sup> Other adverse effects of IFN- $\alpha$ , although much rarer, include depression/suicide risk, neutropenia, alopecia, and liver dysfunction.<sup>17,18</sup> Infliximab, the chimeric monoclonal antibody to tumor necrosis factor (TNF)- $\alpha$ , was reported in one multicenter study to stop inflammatory attacks in 44% and decrease the overall severity of uveoretinitis in 92% of 48 patients over one year of treatment,<sup>22</sup> but data on drug-free remission is still lacking. Adalimumab, a humanized anti-TNF- $\alpha$  monoclonal antibody, was also reported to be effective in selected patients.<sup>25</sup> Adverse effects of TNF-blocking agents include increased risk of opportunistic infections, onset or worsening of autoimmune disorders, central nervous system dysfunction, and thromboembolic events.<sup>16–26</sup>

An expert panel has recommended that infliximab (good-quality evidence) or adalimumab (moderate-quality evidence) may be considered as first-line corticosteroid-sparing therapy in ocular Behçet's disease.<sup>27</sup> There are case reports of the successful use of infliximab administered as an intravitreal injection in ocular Behçet's disease,<sup>28,29</sup> and the systemic use of other biological agents has also been reported in small numbers of patients.<sup>30</sup>

## COURSE AND OUTCOME

The natural history of uveitis in Behçet's disease is one of attacks and remissions over a background of low-grade inflammation. A poor visual outcome can be avoided mainly if the frequency of attacks is limited and irreversible complications are prevented. Decades ago, the visual outcome of Behçet's disease was uniformly dismal, but advances in therapeutics since then have greatly improved visual outcomes, leading to improvements in health and vision-related quality of life.<sup>31</sup>

## Vogt–Koyanagi–Harada Disease

Narsing A. Rao

7.17

**Definition:** Bilateral uveitis featuring exudative retinal detachment, usually associated with meningismus with or without other extraocular manifestations.

**Key Features**

- Bilateral granulomatous posterior or panuveitis.
- Exudative retinal detachment.
- Cerebrospinal fluid pleocytosis.
- Depigmentation of the uvea (sunset glow fundus) in the chronic and recurrent phases.
- Multiple peripheral focal atrophic retinochoroidal lesions in the chronic phase.

**Associated Features**

- Meningitic manifestations: headache, nuchal rigidity.
- Auditory features: tinnitus and sensorineural hearing loss.
- Cutaneous changes: vitiligo, alopecia, and poliosis.

**INTRODUCTION**

Vogt–Koyanagi–Harada disease (VKH) is a bilateral uveitis that is often associated with meningismus and dysacusia during acute phase and alopecia, poliosis, and vitiligo during chronic phase. A recent study revealed the most common presentation of VKH during the acute phase is bilateral posterior or panuveitis associated with serious retinal detachment, whereas during the chronic phase it presents with “sunset glow” fundus changes.<sup>1</sup>

**EPIDEMIOLOGY AND PATHOGENESIS**

VKH disease occurs more frequently in those with darker complexions, such as people of Asian, Hispanic, or Native American descent.<sup>2</sup> The disease appears to affect women more frequently than men and occurs most often in the second to fifth decades of life.

Evidence of increased risk among those with certain HLA genotypes (DRB1 \*0405) indicates that there is a genetically determined susceptibility for VKH disease.<sup>3</sup>

An autoimmune reaction to melanocytes or to their tyrosinase-related peptides has been suggested to play an important role in the pathogenesis.<sup>4</sup>

**OCULAR MANIFESTATIONS**

The diagnostic criteria for VKH disease were suggested by the International Committee on Nomenclature of the disease.<sup>5</sup> The distinguishing features of this disease are bilateral intraocular inflammation associated with retinal detachment or sunset glow fundus changes.<sup>1</sup> Clinically, the disease is categorized into four phases: prodromal, uveitic, chronic, and recurrent.<sup>6</sup>

**Prodromal Phase**

Patients with VKH disease may first visit their internists because of influenza-like symptoms, including fever, headache, and sometimes nausea. Within 1–2 days of the onset of the prodromal phase, the patient typically begins to complain of blurred vision, photophobia, redness of conjunctiva, and ocular pain. The patient also complains of sensitivity of the scalp hair to touch during the prodromal phase.

**Fig. 7.17.1 Fundus in the Uveitic Phase of Vogt–Koyanagi–Harada Disease.** Note the exudative retinal detachment, choroidal folds, and hyperemic optic disc.

**Uveitic Phase**

In the early uveitic phase, cells are present in the anterior chamber and/or the vitreous. In typical cases, the presence of bilateral exudative retinal detachments results in blurring of vision (Fig. 7.17.1). The retinal detachment shows discrete and shallow elevation of the neural retina, with small folds that radiate from the macula. A cloverleaf pattern of detachment is often seen in the posterior fundus. In severe cases, the detachment may become bullous. The optic disc becomes hyperemic and edematous.

**Chronic and Recurrent Phases**

After treatment with systemic corticosteroids, elevation of the neural retina gradually disappears as the subretinal fluid is absorbed. Cells in the anterior chamber and vitreous decrease or disappear. As the uveal inflammation subsides, depigmentation occurs in the fundus, giving it a sunset glow appearance. Small, discrete, and scattered depigmented lesions are seen within the sunset glow fundus (Fig. 7.17.2). Most of these lesions represent degenerated or lost retinal pigment epithelium (RPE).<sup>7</sup> Depigmentation in the corneal limbus is sometimes noted about one month after the onset. This limbal depigmentation is known as Sugiura's sign.<sup>6</sup> The uveitis of chronic VKH may recur. In recurrent cases, anterior uveitis is more predominant than posterior uveitis. Choroidal neovascularization (CNV) may occur in the peripapillary region and the macula. Retinal pigment epithelial proliferation may result in subretinal fibrosis.

**DIAGNOSIS AND ANCILLARY TESTING**

In the early phase of VKH, fluorescein fundus angiography reveals numerous hyperfluorescent dots at the level of the RPE.<sup>8</sup> These dots have a

**Fig. 7.17.2 Sunset Glow Fundus in the Chronic Phase of Vogt–Koyanagi–Harada Disease.** The fundus has a slightly reddish appearance, mainly due to the disappearance of melanocytes in the choroid. Note the numerous small, depigmented lesions of degenerated retinal pigment epithelium.

**Fig. 7.17.3 Fluorescein Fundus Angiography in the Uveitic Phase of Vogt–Koyanagi–Harada Disease.** Note multiple pinpoint and large plaqueoid hyperfluorescent changes.

tendency to gradually enlarge. The dye leaks through the RPE and accumulates in the subretinal space (Fig. 7.17.3). Indocyanine green angiography shows choroidal vascular changes with hypofluorescence dark dots. In the chronic phase, fundus autofluorescence reveals hypo- and hyperautofluorescence changes from RPE damage.

The echographic manifestations include diffuse thickening of the posterior choroid, serous detachment of the retina, vitreous opacities, and posterior thickening of the sclera or episclera. The optical coherence tomography (OCT) often shows foci of retinal detachments (Fig. 7.17.4). OCT in the acute phase will reveal significant choroidal thickening along with the subretinal fluid. Fibrin in the subretinal fluid is not uncommon.

Pleocytosis is seen in the cerebrospinal fluid in approximately 80% of patients within one week and in 97% of patients within three weeks of the onset of the disease.<sup>4</sup> Most of the cells found in the cerebrospinal fluid are small lymphocytes and few melanin-containing macrophages.<sup>9</sup>

## DIFFERENTIAL DIAGNOSIS

Sympathetic uveitis should be differentiated from VKH disease. The only difference between sympathetic uveitis and VKH disease is a history of

**Fig. 7.17.4 Acute Vogt–Koyanagi–Harada Disease.** Optical coherence tomography shows retinal detachment.

penetrating ocular injury or intraocular surgery in patients with sympathetic uveitis and the absence of such a history in patients with VKH disease.

Central serous chorioretinopathy must be differentiated from the uveitic phase of VKH disease. Posterior scleritis often shows exudative retinal detachment. Computed tomography scans and ultrasonography help make the correct diagnosis because they reveal thickening of the posterior sclera.

Acute posterior multifocal placoid pigment epitheliopathy may be confused with VKH disease because of the presence of multiple white–yellow, flat to placoid lesions at the level of the RPE.<sup>10</sup> However, in acute posterior multifocal placoid pigment epitheliopathy there are usually no cells in the anterior chamber or vitreous.

## SYSTEMIC ASSOCIATIONS

### Auditory Signs

Auditory disturbance in VKH disease consists of a hearing loss caused by inner ear dysfunction. Some patients complain of tinnitus and vertigo at the onset. Hearing usually returns to normal within several weeks.

### Neurological Signs

Meningitic manifestations at the onset of the disease may include headache, nausea, and vomiting, but in many cases none of these signs occur. It should be noted that VKH can occur without cerebrospinal fluid pleocytosis.

### Dermal Signs

About 2–3 months after the onset of VKH, vitiligo occurs on the face, hands, shoulders, and back.

### Other Signs

Poliosis (whitened hair of eyelashes) and scalp alopecia (loss of hair) may occur.

## PATHOLOGY

### Uveitic Phase

The pathology of VKH disease is basically the same as that for sympathetic uveitis, with granulomatous inflammation being seen throughout the uveal tissue. The uveal tissues are thickened by diffuse infiltration of lymphocytes, macrophages, and epithelioid cells, and the exudative retinal detachment (Fig. 7.17.5). The epithelioid and giant cells contain pigment granules. Immunohistochemical techniques reveal that the choroidal infiltrate in VKH disease is composed predominantly of T lymphocytes. Class II major histocompatibility complex antigens are expressed on choroidal melanocytes and on the endothelium of the choriocapillaris.<sup>11</sup> Dalen–Fuchs nodules, representing focal granulomas between the RPE and Bruch's membranes, can be observed.

### Chronic and Recurrent Phases

Uvea shows decreased melanocytes resulting in the sunset glow appearance of the fundus. Small, depigmented atrophic lesions, which are seen

**Fig. 7.17.5 The Uveitic Phase of Vogt-Koyanagi-Harada Disease.** The choroid is thickened with inflammatory cell infiltration. Note fluid accumulation in the subretinal space. (Courtesy Professor Hajime Inomata.)

predominantly in the peripheral fundi of the chronic phase, show degeneration or disappearance of the RPE cell, involvement of the choriocapillaris, and formation of chorioretinal scars.<sup>7</sup>

## TREATMENT

VKH disease is treated effectively by the systemic administration of corticosteroids, and, in most cases when the diagnosis is made early in the disease course, the prognosis for visual recovery is favorable. Inadequate treatment, however, can result in recurrent, long-standing uveitis, which may ultimately become intractable. In the early phase, high doses of corticosteroids should be given intravenously or orally. Prednisone 1.5–2 mg/kg is given orally for several weeks, with gradual tapering of the dose once an angiogram reveals the disappearance of dye leakage through the RPE. Topical corticosteroids and cycloplegics are administered until the cells in the anterior chamber disappear.

When the intraocular inflammation cannot be controlled with systemic corticosteroids within 2–3 weeks, or when a patient cannot tolerate the side effects of corticosteroids, immunomodulatory agents may be used; the latter include azathioprine, mycophenolate mofetil, cyclophosphamide, and ciclosporin.<sup>2</sup> The patients who present with chronic phase or chronic recurrent disease often require the concurrent use of immunomodulatory and corticosteroids to suppress the inflammation.<sup>8,12</sup>

## COURSE AND OUTCOME

Uveitis due to VKH disease usually is treated effectively by the systemic administration of corticosteroids. However, posterior subcapsular cataract, secondary angle-closure glaucoma, subretinal neovascularization, and subretinal fibrosis may develop.

# Phacogenic Uveitis

Julie Gueudry, Bahram Bodaghi

# 7.18

**Definition:** Acute or chronic anterior segment and/or vitreous inflammation directed against released or residual lens protein.

## Key Feature

- Anterior uveitis occurring days to weeks after lens capsular surgical or traumatic disruption or spontaneously because of a hypermature cataract.

## Associated Features

- Hypopyon.
- Severe uveitis resembling infectious endophthalmitis.
- Elevated intraocular pressure.

## INTRODUCTION

Phacoanaphylactic, phacotoxic, and phacolytic uveitis represent varying manifestations of inflammatory processes induced by lens material and are referred to as “lens-induced uveitis” or “phacogenic uveitis.” Phacotoxic uveitis and phacoanaphylactic uveitis are the result of an immunological response from retained lens material after cataract extraction or of surgical or traumatic rupture of the lens capsule with subsequent release of lens proteins. The term “phacolytic” refers to nongranulomatous inflammation resulting from lens proteins leaking through an intact lens capsule in an eye with hypermature cataract. Phacolytic glaucoma is considered in this presentation as a lens-induced uveitis, although this remains controversial. A high degree of clinical suspicion is important to recognize these entities to start correct treatment. Moreover, lens-induced uveitis may be difficult to distinguish clinically from infectious postoperative endophthalmitis.

## EPIDEMIOLOGY AND PATHOGENESIS

Lens-induced uveitis is a relatively rare disorder, accounting for <1% of the cases in most uveitis series.<sup>1-3</sup> It was exceedingly rare when intracapsular cataract extraction was performed, and it is now more common as a result of extracapsular cataract extraction technique. Therefore, the peak age of incidence of phacogenic uveitis is in the fifth to seventh decades,<sup>4,5</sup> even though lens-induced uveitis can occur at any age essentially after ocular trauma. The pathogenesis of lens-induced uveitis is still not precisely understood. In fact, the term “phacoanaphylactic” or “phacotoxic” uveitis, previously used, seems misleading. Thus, this reaction does not appear to be a type 1 hypersensitivity reaction or anaphylactoid reaction. Moreover, there is no evidence that lens proteins may be “toxic” to ocular tissues. It was thought by some investigators that lens-induced uveitis is caused by immune rejection of previously “sequestered” lens proteins in an “intact” lens capsule. However, studies have suggested that this entity may be explained, in part, by loss of immunological tolerance to the lens.<sup>5-7</sup>

## OCULAR MANIFESTATIONS

Mostly, phacogenic uveitis occurs as a result of extracapsular cataract extraction or phacoemulsification or after spontaneous, traumatic, or surgical disruption of the lens capsule (Fig. 7.18.1). Typically, its onset is in the days following surgery or trauma, presenting as unilateral pain, redness, photophobia, and visual loss. Acute cases may occur within 24 hours of cataract surgery. A history of retained lens fragments may be obtained. In these cases, the ocular inflammation is severe, with large numbers of

cells in the anterior chamber and vitreous cavity. “Mutton fat” keratic precipitates are generally present, and extensive posterior synechia formation often occurs. Hypopyon can be present. Fragments of lens cortex may be observed in the anterior chamber or in the vitreous cavity (Fig. 7.18.2). The posterior segment is often not visible because of severe vitritis. Intraocular pressure (IOP) may be elevated as a result of trabeculitis, lens debris in angle, or synechiae. Clinical findings associated with severe phacogenic uveitis may be difficult to differentiate reliably from infectious endophthalmitis. However, visual acuity is usually diminished, but there is generally less pain than with acute infectious endophthalmitis.

Subacute or chronic cases are usually less severe, typically developing within 2–3 weeks after surgery or trauma. Clinical signs include cell and flare in the anterior chamber, keratic precipitates, and synechiae. IOP can increase. Epiretinal membrane and macular edema may develop.

Classically, phacolytic glaucoma is seen in patients who have a hypermature lens and an intact lens capsule and have no evidence of traumatic or surgical disruption of the lens capsule. Large, translucent cells with marked flare are seen in the anterior chamber, but keratic precipitates and posterior synechiae are usually absent (Fig. 7.18.3). It may also occur after complicated cataract surgery with loss of lens fragments in the vitreous cavity. IOP is markedly elevated and may often result in corneal edema.<sup>8</sup>

## DIAGNOSIS

Diagnosis of phacogenic uveitis is made on a clinical basis and is based on patient history and clinical examination. However, a complementary examination may be useful to rule out other entities (Table 7.18.1) and secondary complications.

Vitreous or aqueous tap associated with instillation of intravitreal antibiotics injections should be performed when there is any suspicion of infectious endophthalmitis. Gonioscopy may help identify lens material retained in the angle as well as an eventual malposition of an intraocular lens (IOL). Similarly, high-resolution B-scan ultrasonography and/or optical coherence tomography of the anterior segment can detect the position of the lens haptics if IOL-related uveitis is suspected. Posterior segment B-scan ultrasonography can detect posterior segment complications, such as vitritis, retinal detachment and choroidal detachment, retained lens material or intraocular foreign body after ocular trauma. Computed tomography can also help detect intraocular foreign bodies. Laboratory testing should be ordered if inflammation associated with previous uveitis is suspected.

## DIFFERENTIAL DIAGNOSIS

Bacterial/fungal endophthalmitis, low-grade endophthalmitis (e.g., *Propionibacterium acnes*), toxic anterior segment syndrome (TASS) and IOL-related uveitis, intraocular foreign body, flare-up of pre-existing uveitis, and sympathetic ophthalmia should be differentiated from lens-induced uveitis. As mentioned above, in this chapter, phacolytic glaucoma is considered a lens-induced uveitis.

Acute infectious endophthalmitis after penetrating trauma or ocular surgery often presents with signs of severe intraocular inflammation and hypopyon. However, unlike lens-induced uveitis, it is unusual to observe large keratic precipitates. Bacterial or fungal endophthalmitis may be extremely difficult to differentiate from phacogenic uveitis. In such cases, a definitive diagnosis can be established by cytological examination and/or by aqueous and vitreous cultures. TASS is a sterile postoperative response to noninfectious agents, such as impurities in irrigating solutions used during intraocular surgery, anesthetics, and antibiotics, entering the anterior chamber or to improper cleaning or sterilization of instruments.<sup>9</sup> This syndrome usually occurs earlier after surgery (within 1 or 2 days) and may be associated with little or no pain as well as little or no posterior segment

**Fig. 7.18.1 Phacogenic Uveitis Post Trauma.** (A) History of perforating corneal injury with rupture of the lens capsule associated with traumatic cataract. (B) Slit-lamp photograph showing severe anterior inflammation and lens debris in anterior chamber. (C) Note corneal edema caused by increased intraocular pressure.

inflammation. It is also characterized by marked corneal edema. TASS usually responds to intensive topical corticosteroid therapy. IOL-related uveitis is caused by iris or ciliary body chafing from a malpositioned lens implant or from a single-piece IOL in the ciliary sulcus. It is characterized by iris transillumination defects caused by iris chafing. IOL-related uveitis should be treated by reposition or explantation of the intraocular lens (Fig. 7.18.4). Finally, sympathetic ophthalmia always occurs bilaterally, with characteristic yellow-white infiltrates (choroidal granulomas). However, phacogenic uveitis has been seen in association with sympathetic ophthalmia.<sup>10</sup>

**Fig. 7.18.2 Phacogenic Uveitis Post Cataract Surgery.** Fragments of lens cortex may be observed in the anterior chamber and in the angle after complicated cataract surgery.

**Fig. 7.18.3 Phacolytic Glaucoma.** (A) Slit-lamp photograph showing cataract with a dense nucleus setting inferiorly in the liquefied white cortex. (B) History of hypermature cataract associated with elevated intraocular pressure. Note the large cells in the anterior chamber.

## PATHOLOGY

In phacogenic uveitis, aqueous humor cytopathological examination may reveal a zonal granulomatous inflammatory reaction, with polymorphonuclear leukocytes surrounding a nidus of damaged or retained material lens.<sup>11</sup> This is encircled by successive zones of granulomatous inflammation containing multinucleated giant cells and finally a nonspecific layer of mononuclear cells often eosinophils, plasma cells, and histiocytes. In

TABLE 7.18.1 Differential Diagnosis of Phacogenic Uveitis

Acute (days after surgery or trauma)	
Condition	Differentiating Features
Acute infectious endophthalmitis	Rapidly progressive Positive gram stain and culture
TASS	Within the first day after surgery Marked corneal edema Little or no posterior segment inflammation
Flare-up of pre-existing uveitis	Prior history of uveitis systemic or ocular signs of uveitis
Subacute or Chronic (several weeks following surgery or trauma)	
Condition	Differentiating Features
Low-grade endophthalmitis	Positive culture
Fungal endophthalmitis	White intracapsular plaques ( <i>Propionibacterium acnes</i> )
IOL-related uveitis	IOL poorly placed in uveal tissue Iris transillumination defects
Retained intraocular foreign body	Clinical visualization High-resolution and posterior-segment B-scan Ultrasonography CT
Sympathetic ophthalmia	Bilateral disease Prior surgery or trauma in fellow eye

CT, Computed tomography; IOL, intraocular lens; TASS, toxic anterior segment syndrome.

**Fig. 7.18.4 Intraocular Lens (IOL)-Related Uveitis.** Uveitis caused by iris chafing from a sutured iris IOL. One of the haptic is visible through the iris transillumination defect.

phacolytic glaucoma, diagnosis can be established by paracentesis of anterior chamber fluid and examination of the material for macrophages laden with lens material.

TREATMENT

Definitive treatment involves removal of the inciting agent (i.e., the lens or residual lens matter). However, in cases of mild inflammation caused by small retained cortical lens material, intensive topical, periocular, or oral corticosteroids can help manage the intraocular inflammation. In cases of more significant retained lens material, persistent inflammation despite corticosteroid treatment and/or increased IOP, removal of lens material is required, adjunctive to vitrectomy, if necessary. In cases of traumatic disruption of the capsular lens or in cases of phacolytic glaucoma, cataract extraction is indicated. Vitreous tap and injection of intravitreal antibiotics should be performed if there is any suspicion of infectious endophthalmitis. Chronic low-grade endophthalmitis may require surgical capsulectomy with irrigation of the capsular bag, or IOL explantation or even lens-bag complex removal. Treatment of glaucoma that persists even after complete control of inflammation includes either long-term medical treatment or surgical management as trabeculectomy or valve implantation.<sup>12</sup>

COURSE AND OUTCOME

There is often a good outcome with prompt and aggressive management. If the lens is not promptly removed, or in cases of prolonged inflammation and/or increased IOP, corneal endothelial cell loss, glaucoma, hypotony, macular edema, macular scarring, or retinal detachment can lead to visually significant morbidity.

# Sympathetic Uveitis

Sivakumar Rathinam, Narsing A. Rao

# 7.19

**Definition:** Bilateral T cell–mediated autoimmune uveitis after penetrating injury to one eye.

## Key Features

- Bilateral granulomatous posterior uveitis or panuveitis.
- Penetrating ocular injury to the exciting eye.

## Associated Features

- Granulomatous keratic precipitates.
- Papillitis.
- Exudative retinal detachment.
- Dalen–Fuchs nodules.
- Diffuse choroiditis.

## INTRODUCTION

Sympathetic uveitis (sympathetic ophthalmia [SO]) was first described clinically by MacKenzie in 1833, although Hippocrates suggested its existence much earlier (460–370 BC). Fuchs established the pathological definition of SO in 1905, and this resulted in a decrease in its incidence through refinement of surgical technique and prompt disease recognition.<sup>1,2</sup> SO is a sight-threatening disease with a high visual morbidity. Accidental trauma is considered an important risk factor; however, surgical trauma can also result in SO. It is believed to be a cell-mediated autoimmune response to uveal antigens.<sup>3</sup> Aim of the treatment is to promptly and completely suppress this inflammation. Corticosteroids are the mainstay of treatment for initial suppression, which is maintained with addition of immunosuppressive agents.

## EPIDEMIOLOGY AND PATHOGENESIS

SO is a relatively rare disease with a minimum estimated incidence of 0.03 per 100 000.<sup>4</sup> Previous studies report an incidence of 0.2–0.5% after trauma and 0.01% after intraocular surgery.<sup>5,6</sup> However, recently, more cases have been reported after intraocular surgery, including small-gauge sutureless vitrectomy.<sup>7,8</sup> A high index of suspicion is needed to diagnose SO in the early stage.

The exact cause of SO is unknown; however, the common denominator in an overwhelming majority of cases is the presence of a penetrating injury in which wound healing is complicated by incarceration of uveal tissue.<sup>3</sup> There is experimental evidence for a delayed hypersensitivity reaction to tyrosinase peptide antigen or melanocytes, resulting in bilateral nonnecrotizing granulomatous inflammation.<sup>3</sup> The retina seems to be spared in SO; however, mitochondrial oxidative stress could result in apoptosis of photoreceptors.<sup>9</sup> In the past, it was believed that a purulent eye infection would destroy the uveal tissue to such an extent that such eyes do not incite SO.<sup>10</sup> However, there are several reports on occurrence of SO even after purulent endophthalmitis.<sup>11</sup>

## OCULAR MANIFESTATIONS

Clinically, the presentation of SO is quite variable and can manifest either as bilateral posterior uveitis or panuveitis. Acutely, SO classically presents with optic nerve swelling and bilateral exudative retinal detachment, whereas granulomatous “mutton fat” keratic precipitates are usually seen in severe and/or chronic recurrent cases (Figs. 7.19.1 and 7.19.2). The focal,

**Fig. 7.19.1** Fundus photo of a patient with sympathetic ophthalmia with striae and subretinal fluid.

**Fig. 7.19.2** Fluorescein angiography in sympathetic ophthalmia with multiple hyperfluorescent foci of leakage.

elevated infiltrates at the level of the retinal pigment epithelium (RPE) correlate with Dalen–Fuchs nodules seen on histopathological analysis. Inflammation of the optic nerve (papillitis) provides a useful means for monitoring disease progress. Chorioretinal scarring may develop once the inflammation abates, and macular scarring may lead to considerable visual loss.<sup>12</sup>

## DIAGNOSIS

Diagnosing SO requires a high index of clinical suspicion, especially at a time when significant attention is being paid to the injured or surgically managed exciting eye. Roughly 80% occur within the first 3 months after injury; however, this period may range from 5 days to 66 years.<sup>13</sup> The characteristic fluorescein findings consist of multiple foci of leakage at the level of the RPE (Fig. 7.19.3). Hypofluorescent foci (which stain later) are occasionally seen early on angiography. Ultrasonography may demonstrate choroidal thickening and is particularly helpful in the differentiation of bilateral phacoanaphylactic endophthalmitis that presents as a bilateral anterior uveitis. Spectral-domain optical coherence tomography (SD-OCT) (Fig. 7.19.4A, B), can reveal neurosensory detachment with accumulation of fluid in the subretinal space, photoreceptor elongation, loss of the inner segment/outer segment hyperreflective band, and Dalen–Fuch nodules.<sup>14,15</sup>

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes Vogt–Koyanagi–Harada (VKH) disease, bilateral phacoanaphylactic endophthalmitis, and bilateral posterior

scleritis with exudative retinal detachment. If a patient with ocular trauma is treated with corticosteroids for control of inflammation and develops loss of vision in the contralateral eye, it is important to rule out central serous chorioretinopathy because continuing corticosteroids could worsen vision in both eyes. Additionally, any pre-existing uveitis reactivated after trauma should also be considered.

## SYSTEMIC ASSOCIATIONS

The accompanying systemic findings are rare in SO; however, when they are present, they are similar to those seen in VKH disease. These include meningeal signs, headache, dysacusis, tinnitus, alopecia, poliosis, and vitiligo. The only known, reliably differentiating feature of SO from VKH disease is a history of penetrating ocular injury.<sup>12,13</sup>

## PATHOLOGY

The exciting eye and the sympathizing eye demonstrate similar pathology, suggesting involvement of an autoimmune response. The typical histological picture is a bilateral, diffuse nonnecrotizing granulomatous infiltration of the choroid with mononuclear and pigment-containing epithelioid cells, lymphocytes, and giant cells. Dalen–Fuchs nodules project from the RPE/Bruch's membrane complex and correspond to the yellow-white spots observed on ophthalmoscopy. Other pathological changes include inflammatory infiltrates around the melanocytes of the sclera and optic nerve meningeal sheaths.<sup>12</sup> Atypical features, such as nongranulomatous choroiditis or chorioretinal adhesions with the inflammation of choriocapillaris, are occasionally seen, as in chronic VKH disease.<sup>16</sup> In addition to SO, phacoanaphylactic endophthalmitis may coexist secondary to rupture of the lens capsule in the exciting eye.<sup>11</sup>

## PREVENTION

Meticulous and prompt microsurgical wound closure of penetrating ocular injuries may prevent SO. The basic principle is to save the injured eye with useful or potentially salvageable vision and to enucleate badly damaged eyes with no visual function. Once the disease process has commenced, the benefit of enucleation of the traumatized eye is a topic of controversy. Prophylactic corticosteroids treatment has no role in prevention.

## TREATMENT

SO is a sight-threatening disease with high visual morbidity. The objective of treatment is to completely and promptly suppress inflammation and to maintain control for an extended period. Topical, periocular, and systemic corticosteroids are started in severe panuveal inflammation. Pulse intravenous methylprednisolone (up to 1 g daily for 3 days), followed by oral

**Fig. 7.19.3** An active yellow-white focal retinal pigment epithelium (RPE) nodule (black arrowhead) corresponding to a histopathological Dalen–Fuchs nodule in a patient with chronic recurrent sympathetic ophthalmia. Old resolved Dalen–Fuchs nodule (black arrow) and resolved peripapillary exudative detachment (star).

**Fig. 7.19.4** Spectral-domain optical coherence tomography (SD-OCT) in sympathetic ophthalmia. (A) SD-OCT scan of acute sympathetic ophthalmia shows intraretinal edema, serous retinal detachment (arrow), peripapillary edema (star), and choroidal folds (arrowhead). (B) Posttreatment SD-OCT scan shows photoreceptor elongation (arrowhead) and loss of the inner segment/outer segment (IS/OS) hyperreflective band. A hyperreflective lesion is seen at the level of retinal pigment epithelium (arrow) with disruption of IS/OS junction, suggestive of a Dalen–Fuch nodule.

prednisone (1.5–2.0 mg/kg) may be required to suppress inflammation. Immunosuppressive therapy is added to reduce corticosteroid therapy to nontoxic levels (<7.5 mg/day) and to aim for a disease remission. Common agents used include azathioprine (2–4 mg/kg/day), mycophenolate mofetil (1–1.5 g two times daily), and methotrexate (15–25 mg/wk). Alkylating agents, such as cyclophosphamide (2 mg/kg/day) and chlorambucil (0.1–0.2 mg/kg/day) are highly useful in refractory cases.<sup>17,18</sup> Currently, cyclophosphamide and chlorambucil are rarely used since the introduction of biological agents. Biologicals, particularly anti-tumor necrosis factor agents are used in patients who do not respond to the above-mentioned conventional treatment.<sup>19</sup>

## COURSE AND OUTCOME

Although rare, SO is a serious disease that may ultimately result in blindness. The importance of early, aggressive treatment and regular follow-up cannot be overemphasized. Common complications include cataract, glaucoma, macular edema, subretinal fibrosis, retinal detachment, hypotony, and phthisis bulbi. Cataract surgery involves no unusual risks when performed during remission, and its outcomes are dependent on posterior segment complications of the disease.<sup>20</sup> Currently, there are no reliable data on the complications of glaucoma surgery and retinal surgery.

# Idiopathic and Other Anterior Uveitis Syndromes

7.20

Olivia L. Lee

**Definitions:**

- Intraocular inflammation featuring the anterior chamber as the predominant site of inflammation.
- Also referred to as *iritis*, *iridocyclitis*, or *anterior cyclitis*.

**Key Features**

- Inflammatory cell and flare visible in the anterior chamber by slit-lamp biomicroscopy.
- Keratic precipitates, either granulomatous or nongranulomatous, may be present.

**Associated Features**

- Pain, photophobia.
- Hypopyon.
- Posterior synechiae.
- Cataract formation.

**INTRODUCTION**

Anterior uveitis is the most common form of intraocular inflammation. The diagnosis of anterior uveitis is based on clinical findings consistent with inflammation primarily located in the anterior chamber.<sup>1</sup> On slit-lamp biomicroscopy, anterior chamber cell and flare can be seen as the major indicator of inflammation affecting the iris and the ciliary body. Typically, the diagnosis is straightforward, although other conditions, such as panuveitis, endophthalmitis, and ocular tumors, can begin with a presentation mimicking anterior uveitis. Although occasionally self-limiting, in most cases anterior uveitis can be treated simply with topical corticosteroids and cycloplegic agents. However, those cases of chronic inflammation or multiple recurrent episodes can be more difficult to manage.

**EPIDEMIOLOGY AND PATHOGENESIS**

Anterior uveitis accounts for most cases of uveitis with an annual incidence of 12 cases per 100 000.<sup>2</sup> The most common association is with haplotype human leukocyte antigen (HLA) B27 (see Chapter 7.14). Depending on the population, in some series, HLA B27 is associated with up to 50% of cases of anterior uveitis,<sup>3</sup> with approximately 45% of these being associated with spondyloarthropathy.<sup>4,5</sup> However, when no identifiable etiology is attributed, the classification of idiopathic anterior uveitis is made. The lifetime cumulative incidence of idiopathic acute anterior uveitis is 0.15%.<sup>6</sup> Males and females are affected equally.

A systemic disease association, including juvenile idiopathic arthritis (JIA), sarcoidosis, tubulointerstitial nephritis and uveitis syndrome (TINU) or Behçet's disease, and HLA B27-associated conditions, should be considered. The ophthalmologist can play a role in making the diagnosis of such systemic conditions when anterior uveitis presents in a patient with no known prior diagnosis. Other ocular conditions, such as ocular ischemic syndrome, neovascular glaucoma, and pigment dispersion syndrome, can either mimic or produce anterior chamber inflammation. Trauma can also produce iritis, and when the history is indicative, careful examination for intraocular foreign body and lens capsule rupture should be performed.

Nevertheless, most cases of anterior uveitis have no specific etiology and are classified as idiopathic. If a patient tests positive for HLA B27 but

has no extraocular manifestation, the term *idiopathic anterior uveitis* should not be used. The pathogenesis of anterior uveitis in idiopathic cases is presumed to be autoimmune. Blood–aqueous barrier disruption in acute anterior uveitis has been demonstrated by laser cell and flare photometry.<sup>7</sup> Compared with healthy controls, patients with a history of idiopathic anterior uveitis have low-grade systemic inflammation, even at the time when uveitis is quiescent. Furthermore, their monocytes generate higher levels of innate immune responsiveness when stimulated *ex vivo*, suggesting these patients with uveitis but no identifiable systemic autoimmune condition have altered innate immunity that plays a role in the development of anterior uveitis.<sup>8</sup>

Anterior uveitis is presumed to be noninfectious but may be preceded by a nonocular infectious condition. Various pathogens affecting the gastrointestinal, urinary, and respiratory tracts have been implicated in triggering a bout of intraocular inflammation. The prevalence of antibodies to these pathogens is higher in patients with a history of multiple recurrences of anterior uveitis compared with those with fewer recurrences and normal controls.<sup>9</sup>

Recent evidence of viral infectious agents in the intraocular fluid of eyes with anterior uveitis has led to infectious theories of the pathogenesis of conditions previously thought to be noninfectious, such as Posner–Schlossman syndrome (PSS) and Fuchs' heterochromic iridocyclitis (FHI).<sup>10</sup> Cytomegalovirus (CMV) has been recognized to have an association with anterior uveitis in immunocompetent patients without chorioretinitis, particularly in Asia.<sup>11</sup> Identification of other viral organisms in the aqueous fluid taken from eyes with anterior uveitis, including Epstein–Barr virus, human herpesvirus, and human parechovirus, have been demonstrated by polymerase chain reaction (PCR), but the clinical implication of these findings are still unknown.<sup>12,13</sup>

**OCULAR MANIFESTATIONS**

Presenting symptoms of acute anterior uveitis include pain, redness, photophobia, and sometimes blurred vision. Some patients, particularly those with JIA, can be asymptomatic. The onset is typically acute but can also occur insidiously with exacerbating severity over the period of  $\geq 1$  week. The patient may complain of unilateral symptoms but may have asymmetrical, bilateral inflammation on examination.

Slit-lamp biomicroscopy will reveal anterior chamber cell and flare. Ciliary flush in the form of limbal vascular injection is frequently seen. Keratic precipitates on the corneal endothelium are a common finding (Fig. 7.20.1). These cellular deposits are most often localized within Arlt's triangle as a result of aqueous currents in the anterior chamber. However, viral anterior uveitis is associated with keratic precipitates in a diffuse pattern. Large, greasy keratic precipitates are granulomatous and suggestive of etiologies, such as sarcoidosis, tuberculosis, Vogt–Koyanagi–Harada syndrome, toxoplasmosis, and sympathetic ophthalmia. Stellate, nodular, and dendritic keratic precipitates are seen in infectious uveitis.<sup>14,15</sup>

Hypopyon is a collection of inflammatory cells seen occupying the inferior aspect of the anterior chamber as the exudate settles dependently as a result of gravity. The presence of a hypopyon suggests active infection but can occur with both acute uveitis and recurrent anterior uveitis. Hypopyon uveitis is seen in Behçet's disease and HLA B27-associated uveitis, as well as in rifabutin-induced anterior uveitis and in infectious conditions, such as microbial keratitis and endophthalmitis.<sup>16</sup> Fibrin may accumulate in the anterior chamber as well, causing the otherwise mobile inflammatory cells in the anterior chamber to move slowly within the aqueous humor. The

**Fig. 7.20.1 Keratic Precipitates.** Collections of inflammatory cells can be seen on the corneal endothelium. Their appearance, for example as stellate in viral uveitis (A) or “mutton fat” in granulomatous inflammation (B) can be suggestive of the etiology of anterior uveitis.

fibrin may organize into a membrane, partially or completely occluding the pupil.

Any level of intraocular pressure (IOP) can be seen during episodes of active anterior uveitis. The pressure may be low because of ciliary body shutdown and reduced aqueous production and returns to normal after resolution. In long-standing, chronic cases, intractable hypotony may occur in eyes where the ciliary body does not recover. However, elevated pressure can be seen during the acute phase of the disease, particularly with viral anterior uveitis, PSS, and uveitic glaucoma. An open angle can be blocked by inflammatory cells and fibrin, decreasing aqueous outflow. Over time, peripheral anterior synechiae formation can lead to complete angle closure and iris bombé. This is further complicated by the possibility of corticosteroid response glaucoma in a patient receiving treatment with corticosteroids. Therefore, the pathogenesis of elevated IOP in eyes with anterior uveitis can be multifactorial.

Previous episodes of anterior uveitis will lead to sequelae of anterior chamber inflammation that can be seen on examination (Fig. 7.20.2). These findings include old, pigmented, or crenated keratic precipitates; peripheral anterior synechiae; posterior synechia or remnants of broken

**Fig. 7.20.2 Sequelae of Chronic Anterior Uveitis.** As a result of chronic anterior chamber inflammation, pupillary membrane formation is seen. Synechiae are present as iridocorneal adhesions in this patient with HLA B27–associated chronic anterior uveitis (A). Band keratopathy is a common corneal finding in patients with juvenile idiopathic arthritis (JIA)–associated chronic anterior uveitis (B).

posterior synechiae on the anterior lens capsule; pupillary membrane; or occlusion pupillae. Calcific band keratopathy can be seen as deposition of calcium on the cornea within the interpalpebral zone and is indicative of long course of chronic inflammation.

## DIAGNOSIS AND ANCILLARY TESTING

The diagnosis of anterior uveitis can be made on the basis of clinical examination consistent with inflammation that affects primarily the anterior chamber but does not exclude the possibility of associated inflammatory findings, such as spillover anterior vitreous cells or cystoid macular edema. The presence of anterior chamber reaction in the form of cells and flare can be seen by slit-lamp biomicroscopy. Combined with clinical history and usual symptoms of pain, redness, and photophobia, the diagnosis is typically straightforward.

Although unnecessary for making the diagnosis, measurements of aqueous flare, made using laser flare photometry, can provide the ability to monitor anterior chamber reaction in a quantitative fashion during and

between episodes.<sup>7,17–19</sup> Anterior chamber paracentesis is a safe and useful outpatient procedure,<sup>20</sup> which can aid in the diagnosis of idiopathic anterior uveitis because it is a diagnosis of exclusion. The aqueous sample can be used for culture when an infectious etiology is suspected. However, newer techniques for aqueous humor analysis are more sensitive than culture. PCR can be performed on aqueous samples to identify a range of infectious organisms, such as CMV, herpes simplex virus (HSV), varicella zoster virus (VZV), rubella, and *Mycobacterium tuberculosis*. Furthermore, histopathology can be useful in identifying masquerade syndromes, such as leukemia, retinoblastoma, and phacoantigenic uveitis.<sup>21</sup>

## DIFFERENTIAL DIAGNOSIS

Idiopathic anterior uveitis is a diagnosis of exclusion. In some cases, the patient's history (e.g., recent cataract surgery or antecedent nonpenetrating ocular trauma) makes the diagnosis obvious. At times, review of systems or examination findings may be suggestive of a particular etiology, emphasizing the importance of a thorough medical history and careful examination. For example, a history of recurrent, alternating episodes of acute anterior uveitis in a patient with joint pain and keratoderma blennorrhagia is suggestive of HLA B27-associated anterior uveitis. A clinical diagnosis of herpetic iritis can be made with a constellation of typically associated examination findings, such as iris transillumination defects, stellate keratic precipitates, and elevated IOP. In this case, anterior chamber paracentesis for viral PCR could be performed to confirm the diagnosis. Otherwise, there is no consensus as to whether or not a single, isolated episode of anterior uveitis necessitates a systemic workup. If consistent with the clinical picture, including demographics and geographical locale, such a workup should aim at ruling out treatable infectious etiologies, such as syphilis, Lyme disease, leprosy, and tuberculosis, as well as conditions with systemic ramifications, such as HLA B27 haplotype, sarcoidosis, JIA, Behçet's disease, and TINU. Some cases of presumed idiopathic anterior uveitis are later found to be associated with a specific disease entity, particularly if extraocular symptoms present later.

## PATHOLOGY

Histological examination of the anterior uvea in experimental melanin-induced uveitis (EMIU), an animal model of anterior uveitis, reveals mononuclear cells, neutrophils and T cells.<sup>22</sup> Monocytes may be seen marginating in the iris vessels. Evidence suggests that cytokines produced by uveal macrophages may play a role in the development of uveitis.<sup>23,24</sup> Aqueous samples taken from patients with idiopathic anterior uveitis demonstrate CD4+ T cells with increased interleukin-2 receptor expression<sup>25,26</sup> consistent with findings of CD4+ T cell infiltration of the anterior uvea in EMIU, which responds to treatment with anti-CD4+ antibody.<sup>27</sup>

## TREATMENT

Corticosteroids are the mainstay of therapy for the treatment of noninfectious anterior uveitis and have both anti-inflammatory and immunosuppressive properties, irrespective of the etiology of the inflammatory response (traumatic, infectious, autoimmune, postoperative, etc.) These changes to the immune system are temporary and cease within days of discontinuation of corticosteroid use. Various topical corticosteroids are available for ophthalmic use; the more potent preparations contain acetate and penetrate intact cornea. Frequent administration is typically recommended, and patients are commonly instructed to apply this medication every 1–2 hours while awake during an acute episode of severe anterior uveitis. Once an improvement in cell and flare is observed, slow tapering of the corticosteroid medication can begin. In refractory cases, periocular or systemic corticosteroid may be required to achieve quiescence. Fortunately, topical corticosteroids for ophthalmic use have not been reported to be associated with teratogenicity, but systemic corticosteroids have been associated with the formation of orofacial clefts.<sup>28</sup> Therefore, in the setting of pregnancy, regional corticosteroid injection would minimize the potential for systemic absorption affecting the fetus.

Cycloplegic/mydriatic agents are given to prevent the formation of, and possibly break, posterior synechiae. In addition, these agents reduce pain and photophobia caused by inflammation of the ciliary muscle. If the intraocular pressure is elevated, glaucoma medication should be employed. However, if possible, prostaglandin analogues and pilocarpine should be avoided, although not contraindicated, because of the theoretic effect on the blood–aqueous barrier.<sup>29,30</sup> Topical nonsteroidal anti-inflammatory

drugs (NSAIDs) can be given for uveitic cystoid macular edema associated with chronic anterior uveitis; alternatively, or in refractory cases, periocular corticosteroid injection can be given for this indication as well.<sup>31</sup>

It is important to consider that prolonged and frequent use of topical corticosteroids is not prudent in certain situations. The risk of cataract formation and glaucoma should be considered in patients with phakia and those who react to corticosteroid, respectively. Because of the risk of amblyopia secondary to cataract formation, it is preferable to avoid  $\geq 3$  times daily dosing of topical corticosteroids in pediatric patients.<sup>32</sup> Therefore, in children with chronic anterior inflammation, such as JIA-associated uveitis, systemic treatment with a corticosteroid-sparing agent is usually necessary. In patients with chronic anterior uveitis who are unable to achieve or sustain remission after corticosteroid taper, as well as those who cannot tolerate the necessary dosage or frequency of corticosteroid required, systemic immunosuppression should be considered.

Surgical intervention is seldom recommended as a treatment for anterior uveitis because surgical trauma itself will incite further ocular inflammation. Typically, surgery to address complications of chronic uveitis is deferred until a period of quiescence has been achieved. However, surgical lens removal is the treatment of choice for active lens-induced uveitis and uveitis glaucoma hyphema (UGH) syndrome. In these conditions, removal of the phakic or pseudo-phakic lens is the definitive treatment to address the inciting cause of ocular inflammation.

## FUCHS' HETEROCHROMIC IRIDOCYCLITIS

FHI is an anterior uveitis syndrome that may present with variable signs and symptoms, often beginning insidiously. Young adults are affected, and the disease is usually unilateral, although 15% of cases are reported to be bilateral.<sup>33</sup> Patients typically do not have the usual symptoms of pain, redness, and photophobia. Typical manifestations include low-grade chronic anterior chamber reaction, iris heterochromia, stellate keratic precipitates, and bridging iris vessels. Low-grade anterior vitritis is present and may cause symptomatic floaters. Because of the subtleties of its clinical presentation, the diagnosis of FHI may be delayed,<sup>34</sup> and the patient may not become symptomatic until cataract formation becomes visually significant.

Iris heterochromia, the hallmark of this syndrome, was initially described by Fuchs in 1906<sup>35</sup> and may be noticed by the patient or family members. Iris stromal atrophy leads to the color change of the iris on the affected eye. In a patient with dark irises, the involved eye takes on a lighter color. In a patient with pale-colored eyes, reverse heterochromia occurs as the darker pigmented posterior iris becomes exposed as a result of anterior iris stromal atrophy. In a patient with bilateral FHI, heterochromia will not be evident, and characteristics of the iris, including a moth-eaten appearance with patchy areas of transillumination defects, may be the only consistent findings.

Fine, stellate keratic precipitates are commonly seen in a diffuse distribution. However, all types of keratic precipitates, including globular, infiltrating, dendritiform, stippled, cruciform, and "mutton fat" varieties, have been reported.<sup>36,37</sup> Fine neovascularization with bridging vessels over the angle are seen on gonioscopy. These vessels have a tendency to hemorrhage during anterior chamber paracentesis, a phenomenon termed "Amsler's sign."<sup>38</sup> Similarly, hyphema is expected to occur intraoperatively during cataract surgery but does not typically complicate the procedure.

Cataract is seen in over 80% of eyes with FHI and elevated IOP in 25%–60% of patients, arising either from the inflammation or from corticosteroid therapy.<sup>33,39</sup> Posterior subcapsular cataracts are most common, and patients tend to tolerate cataract extraction without complication. Glaucoma develops in 6.3%–59% of patients, and 25%–60% of those individuals require a filtering procedure during the course of treatment. Most importantly, the complications from chronic inflammation in FHI do not usually include posterior synechiae or cystoid macular edema, unlike other anterior uveitis entities.

The use of NSAIDs is not useful in the treatment of FHI, as there is little effect on the severity or course of intraocular inflammation. Treatment is directed toward the management of complications of the condition, including cataract, glaucoma, and, occasionally, visually significant vitreous opacities. The prognosis for eyes with FHI is good, with almost all eyes achieving visual acuity of 20/40 or better.<sup>40–42</sup>

Once thought to be idiopathic, there is now evidence to support that FHI is linked to rubella virus. Isolation of the organism from intraocular fluids by using PCR and reverse transcription-PCR is difficult.<sup>43</sup> Local antibody production is indicated by a Goldmann–Witmer coefficient (GWC) of  $>3$ . The presence of rubella infection in FHI eyes has been confirmed

by GWC in several studies.<sup>44-47</sup> Furthermore, epidemiological data suggest that FHI has become less common among patients born after the introduction of the US rubella vaccination program compared with foreign-born and older American populations for whom rubella vaccination was not available.<sup>48</sup>

## POSNER–SCHLOSSMAN SYNDROME

Unilateral attacks of mild nongranulomatous anterior uveitis with elevations in IOP are the hallmark of PSS. Acute attacks of glaucomatocyclitic crisis last from a few hours to several weeks and may be recurrent. Between episodes, IOP and aqueous outflow facility return to normal. Affected patients tend to be younger (age 20–50 years) with a male predilection.

Symptoms of an acute attack of PSS may include unilateral blurred vision and pain. Clinical examination reveals mild anterior chamber reaction and small- to medium-sized nongranulomatous keratic precipitates. There may also be associated corneal edema, which resolves with lowering of the IOP. IOP elevation is usually as high as 40–60 mm Hg, which results from blockage of the trabecular meshwork with mononuclear cells.<sup>49</sup>

Attacks of PSS are thought to be benign. Transient S-cone response reductions on electroretinography<sup>50</sup> and optic nerve head blood flow alterations<sup>51</sup> have been described. Mild loss of endothelial cell density, particularly with recurrent attacks, has been noted on specular microscopy.<sup>52</sup> Both mild and advanced glaucomatous optic nerve cupping and visual field loss have been reported.<sup>53,54</sup>

The exact etiology of PSS is unknown. Since it was first described, a variety of noninfectious etiological theories were proposed, including autoimmune dysregulation,<sup>55</sup> allergy,<sup>55-58</sup> and abnormality of the ciliary vasculature.<sup>59,60</sup> Infectious etiologies were not entertained initially because of the episodic nature of the acute attacks. In modern literature, evidence has emerged to support various infectious theories associated with several distinct organisms: CMV,<sup>11,15,61-63</sup> *Helicobacter pylori*,<sup>64</sup> VZV,<sup>65</sup> HSV,<sup>66</sup> and *Borrelia burgdorferi*.<sup>67</sup> Enzyme-linked immunosorbent assay of serum tested positive for *H. pylori* in 80% of patients with PSS compared with 56% in controls.<sup>64</sup> PCR of aqueous fluid has been used to confirm the presence of CMV.<sup>11,61-64</sup> The lack of PCR positivity during times of quiescence and a positive Goldmann–Whitmer coefficient, as well as therapeutic response to anti-infectives suggest a causal relationship, with the largest body of evidence supporting CMV as an etiological agent.<sup>64</sup> PSS has also been described in association with peptic ulcer disease<sup>58,69</sup> and genetic marker HLA-Bw54.<sup>68</sup>

The aim of treatment is to address the anterior segment inflammation and to lower IOP. Topical corticosteroids and ocular hypotensive medications are sufficient to control these attacks but not to prevent recurrences. Without intervention, these attacks usually resolve. However, cases of nonarteritic anterior ischemic optic neuropathy secondary to acute glaucoma associated with PSS have been reported,<sup>69,70</sup> suggesting the need to treat IOP even if it is self-limiting. IOP in PSS responds to topical hypotensives more readily compared with that in primary open-angle glaucoma; apraclonidine alone lowers IOP by 50% over a 4-hour period.<sup>71</sup> Occasionally, surgical intervention is necessary to control raised IOP.<sup>72</sup>

## DRUG-INDUCED ANTERIOR UVEITIS

Anterior uveitis can arise as a result of drug-induced ocular inflammation but the incidence is <1%.<sup>73</sup> The offending agent may have been administered systemically, topically, or intracamerally. Diagnosis of drug-induced anterior uveitis relies on suspicion on the part of the clinician with consistent time sequence between drug administration and clinical event, as well as resolution of the condition after withdrawal of the drug. The most commonly implicated drugs are intravenous or intravitreal cidofovir, systemic rifabutin, systemic sulfonamides, oral bisphosphonates, topical metipranolol, topical and intravitreal corticosteroids and, most recently, oral moxifloxacin.<sup>74-77</sup> Cidofovir causes a mild anterior chamber reaction with a fibrinous response; the anterior vitreous is involved in half the cases.<sup>78</sup> Rifabutin-induced uveitis occurs in the dose range of 200–1800 mg and is more common in immunocompromised individuals but has been reported in immunocompetent patients also.<sup>79</sup> The anterior chamber reaction is severe and fibrinous, accompanied by hypopyon that resolves with intensive topical corticosteroid therapy.<sup>80</sup> Oral moxifloxacin has been reported to be associated with bilateral anterior uveitis, pigment dispersion, transillumination defects, and atonic pupils.<sup>74-77</sup> Less frequently, other fluoroquinolones have also been implicated to cause this reaction.<sup>77</sup> The mechanism

behind ocular inflammation secondary to medication is unknown but may represent a hypersensitivity reaction.

## SCHWARTZ–MATSUO SYNDROME

Anterior segment inflammation with elevated IOP and open anterior chamber angle is caused by rhegmatogenous retinal detachment in Schwartz–Matsuo syndrome.<sup>81,82</sup> This is not a true anterior uveitis, as the anterior chamber is filled with pigmented cells representing photoreceptor outer segments.<sup>83</sup> Retinal tears or dialysis anterior to the anterior vitreous base allow rod outer segments to migrate from the subretinal space through the peripheral retinal break into the aqueous humor, thus obstructing aqueous outflow.<sup>82</sup> The condition is not responsive to corticosteroid therapy. IOP can be as high as 60–70 mm Hg and is responsive to aqueous suppressants. Upon repair of the retinal detachment, the condition resolves, and IOP normalizes.

## ELLINGSON SYNDROME

UGH syndrome, also known as *Ellingson syndrome*, was first described by Ellingson in 1978.<sup>84</sup> This form of anterior uveitis is secondary to chaffing of the uvea by an intraocular lens and is associated with elevated IOP and bleeding of uveal vessels. The syndrome was originally described with first-generation anterior chamber IOLs which led to haptic or optic contact with iris and angle structures. The size, rigidity, shape, and design of earlier IOLs caused lens movement and mechanical chaffing on the iris and angle structures.<sup>85</sup> However, UGH syndrome may also occur with sulcus IOLs and posterior chamber lenses implanted partially or completely within the capsular bag,<sup>86</sup> as well as cosmetic iris prosthetic devices<sup>87,88</sup> and Soemmering's ring.<sup>89</sup> Irritation of the uveal tissue creates pigment dispersion as well as breakdown of the blood–aqueous barrier. Iris chaffing leads to localized transillumination defects in the area of mechanical contact with the iris stroma. Release of erythrocytes, lymphocytes, and pigment into the anterior chamber result in elevated IOP as a result of clogging of the trabecular meshwork. Iris neovascularization can occur, and bleeding from these vessels result in recurrent microhyphema, hyphema, or, occasionally, vitreous hemorrhage.<sup>90</sup> Although the diagnosis of UGH is made clinically, ultrasound biomicroscopy<sup>91</sup> can aid in visualization of IOL malposition and the contact between the IOL optic and/or haptics with uveal structures. Medical management with topical corticosteroids and cycloplegic agents are used in the acute management of UGH syndrome. However, UGH syndrome is an indication for IOL explantation,<sup>92</sup> which is a definitive treatment to resolve recurrent inflammation caused by uveal irritation.

# Pars Planitis and Other Intermediate Uveitis

John A. Gonzales, Aliza Jap, Soon-Phaik Chee

7.21

**Definition:** Intraocular inflammation primarily involving the anterior vitreous, pars plana ciliaris, and peripheral retina.

### Key Features

- Typically bilateral.
- Inflammatory cells in the anterior vitreous.
- Aggregates of inflammatory cells (snowballs) in the vitreous.
- White exudate (snowbank) on the inferior pars plana.
- Peripheral retinal vascular sheathing adjacent to exudates.
- Cystoid macular edema.
- Vitreous opacity.
- Mild or absent anterior chamber cell and flare.

### Associated Features

- Patients are generally young, with a mean age at presentation of 23–31 years, and it is uncommon in older adults.
- Floaters and blurry vision are the most common symptoms.
- Mild pain, photophobia, and redness are less common.
- Possible complications include vitreous traction, rhegmatogenous retinal detachments, neovascularization of the retina or optic disc, vitreous hemorrhage, posterior subcapsular cataract, glaucoma, inferior endophthalmitis, posterior synechiae, retinal or anterior segment neovascularization, and secondary vasoproliferative tumors.<sup>1</sup>

## INTRODUCTION

*Intermediate uveitis* (IU) is the term recommended by the Standardization of Uveitis Nomenclature working group for intraocular inflammation when the primary site of involvement is the vitreous.<sup>2</sup> It includes inflammation occurring at the pars plana and the peripheral retina. Pars planitis is a subset of IU in which snowbanks or snowballs are prominent features and there is no associated systemic or infectious disease.<sup>2</sup>

## EPIDEMIOLOGY AND PATHOGENESIS

IU is relatively uncommon, accounting for 1%–26% of all cases of uveitis,<sup>3,4</sup> with an annual incidence of 1.5–2.1 per 100 000 person years in the general population.<sup>5–8</sup> It occurs mainly in children and young adults with a mean age at presentation of 23–31 years, and it is uncommon in older adults.<sup>4</sup>

It is thought to be an autoimmune process, and there is considerable evidence to show an association between multiple sclerosis (MS) and IU. The prevalence of MS in patients with IU ranges from 7% to 16%.<sup>5,9–11</sup> Conversely, the prevalence of uveitis in patients with MS is about 1%, and in these patients, IU is the most common form of involvement.<sup>4,6</sup> Uveitis may be the presenting symptom in 25% of cases, and it may precede the diagnosis of MS by 3–9 years.<sup>10</sup> Furthermore, various studies have also found an association between human leukocyte antigens (HLAs) (in particular HLA DR15), with IU and MS.<sup>7</sup> Similarly, the association with sarcoidosis<sup>9,12</sup> as well as the involvement of family members with similar HLA typing also suggests an autoimmune mechanism.<sup>13</sup>

In some cases, an infection, such as tuberculosis (TB), syphilis, Lyme disease, cat scratch disease, or human T-lymphotropic virus type 1 infection, may be the inciting cause for the immune response.<sup>14–18</sup>

Histopathological studies of the snowbanks show glial and vascular proliferation, as well as lymphocytic infiltration of the peripheral retinal veins. The glial component comprises vitreous collagen and fibrous astrocytes, whereas lymphocytic infiltrates are composed mainly of T helper cells. These further suggest that IU is an autoimmune process. The choroid is relatively spared.<sup>13,19</sup>

## OCULAR FINDINGS AND COMPLICATIONS

IU is typically a bilateral disease (Table 7.21.1)<sup>8,20,21</sup> with a chronic, slowly progressive course and episodes of relapses in some patients.<sup>5,20</sup> As the primary site of involvement is the vitreous, the most common symptoms are blurred vision and floaters.<sup>5</sup> Pain, photophobia, and redness are less common symptoms (4%–7%),<sup>5</sup> and it may be asymptomatic especially in children (7%–25%).<sup>5,21</sup>

Although anterior chamber inflammation may be present in up to 57% of cases,<sup>5,21,22</sup> it is usually mild<sup>5,21</sup> and posterior synechiae is uncommon (6%–14%).<sup>5,8,21,22</sup> A linear configuration of keratic precipitates, similar to that seen in autoimmune endotheliopathy, has also been described in a small number of cases (Fig. 7.21.1). There may also be concomitant corneal edema.<sup>20</sup>

The predominant finding is vitritis, and the vitreous cells may coalesce to form snowballs. Another frequently seen finding is that of snowbanks, which consist of a conglomeration of inflammatory exudates at the pars plana. These snowbanks are generally found inferiorly but may extend throughout the pars plana.<sup>5,22</sup> These inflammatory changes may be associated with peripheral vascular sheathing<sup>5,9,21,22</sup> and as a result, neovascularization of the pars plana (Fig. 7.21.2), retina, or optic disc may occur.<sup>5,21,22</sup> This can lead to vitreous hemorrhage, which is more commonly seen in children,<sup>12</sup> and/or retinal detachment. However, neovascular glaucoma is rarely seen. Inferior peripheral elevations are found in about 13% of cases<sup>21,23</sup> and may be caused by retinoschisis, and/or tractional or exudative retinal detachment.

The main causes of visual loss in IU are cystoid macula edema (CME) (Fig. 7.21.3),<sup>5,8,20–22</sup> epiretinal membranes (ERMs),<sup>5,20,22</sup> and cataract formation.<sup>5,8,19,20</sup> Glaucoma is also seen in 11%–14% of cases<sup>8,20,22</sup> and may be

TABLE 7.21.1 Main Clinical Features and Complications of Intermediate Uveitis

Clinical Features	Percentage <sup>5,8,19–21</sup>
Bilaterality	>80%
Blurring of vision	74%
Floaters	61%
Vitritis/snowballs/snowbanks	63–90%
Peripheral vascular sheathing	23–90%
<b>Complications</b>	
Cystoid macula edema	20–63%
Cataract	25–83%
Epiretinal membrane	6–36%
Neovascularization	4–23%
Vitreous hemorrhage	17–24%
Optic disc swelling	12–75%
Glaucoma	11–14%
Band keratopathy	3–17%

**Fig. 7.21.1** Slit-lamp photograph of a linear arrangement of keratic precipitates in an eye with intermediate uveitis.

a direct result of chronic inflammation or secondary to corticosteroid therapy. Other complications include optic disc swelling<sup>3,20,22</sup> and band keratopathy.<sup>20,22</sup>

## DIAGNOSIS

The diagnosis of pars planitis is based on meticulous history and examination and ancillary tests to exclude infective causes and associated systemic diseases. Specifically, the history and examination should include the presence of skin lesions, which may indicate sarcoidosis, syphilis, TB, or Lyme disease. A history of fever, cough, or night sweats may suggest TB or sarcoidosis. Arthralgia may be a symptom of Lyme or Whipple's disease. If an infectious cause is suspected, the history should include travel to areas where the disease is endemic, trekking, or contact with cats, as appropriate. Patients with MS may have had previous episodes of neurological involvement, such as optic neuritis.

In addition to diagnosis, ancillary tests are also useful in assessing the severity of disease. Fundal photography and fluorescein angiography allow for objective records of extent of vitritis and/or vascular sheathing, respectively. Ultrasonography is especially useful in evaluating and monitoring the progression in eyes where examination of the posterior segment is limited by media opacity or a small pupil. Optical coherence tomography is a valuable tool in assessing macular changes, such as CME, during the course of the disease as well as during treatment.

Diagnostic tests should include complete blood count; tuberculin sensitivity test; angiotensin-converting enzyme and lysozyme levels; serology for syphilis, Lyme disease, TB, and other infectious diseases, as indicated; and chest radiography for TB and/or sarcoidosis. Magnetic resonance imaging of the brain for white matter lesions may be advisable in populations with a high prevalence of MS.

In older patients, the possibility of lymphoma should also be considered. Ocular involvement, including IU, may be the first presentation of primary central nervous system lymphoma, and the mean age of onset in these patients is about 60 years.<sup>24,25</sup> A definitive diagnosis of ocular lymphoma often requires vitreous biopsy, and if the cellular quality of the sample is inadequate for cytology, molecular analysis of immunoglobulin heavy chain (IgH) and T-cell receptor (TCR) gene arrangement, flow cytometry, or cytokine analysis of vitreous interleukin-10 (IL-10) to IL-6 ratio are useful biomarkers with high sensitivity and specificity.<sup>26,27</sup>

## MANAGEMENT

Up to one third of patients have mild inflammation and good vision and do not require treatment.<sup>4</sup> However, if visual loss results from CME, vitritis, or neovascularization, treatment should be started early, and the duration of treatment in these eyes is often prolonged.

## Medical Management

Corticosteroids are the first line of treatment and may be given via the topical, periocular, intravitreal, or systemic route. Local administration avoids the protean complications of systemic corticosteroids. However, the ocular penetration after topical applications of corticosteroids is poor, and in view of the chronic nature of IU and the limited duration of effectiveness of periocular and intravitreal medications, the injections often have to be repeated. Cataract progression and elevated intraocular pressures are common complications of intravitreal corticosteroids. In addition, periocular injections carry risks of ocular perforations, and intravitreal injections of triamcinolone or implants of sustained release formulations of corticosteroids, such as flucinolone or dexamethasone, pose risks of endophthalmitis, vitreous hemorrhage, and/or retinal detachment. If the inflammation is refractory or the patient is unable to tolerate corticosteroids, various systemic immunosuppressive/immunomodulatory agents, such as azathioprine, methotrexate, tacrolimus, mycophenolate mofetil, cyclosporine, or interferon- $\alpha$ 2a (IFN- $\alpha$ 2a,<sup>28–33</sup> may be used. With the advent of the biologicals, tumor necrosis factor (TNF) inhibitors have been used for the management of intermediate uveitis, particularly when it exhibits recalcitrance to antimetabolites or calcineurin inhibitors.<sup>34</sup> Additionally, the US Food and Drug Administration has approved the use of adalimumab for noninfectious intermediate, posterior uveitis, and panuveitis. Although TNF inhibitors (particularly adalimumab and infliximab) can be effective in managing inflammation in intermediate uveitis, given the incidence of MS in intermediate uveitis, referral to a neurologist for consideration of neuroimaging to rule out features of a demyelinating process is recommended. Anti-TNF agents can hasten the development of MS in those predisposed to developing the neurological disease or make the condition worse if it is present.<sup>35,36</sup>

In eyes with persistent CME despite having achieved control of the inflammation, in addition to supplemental local therapy with periocular or intravitreal corticosteroids, the intravitreal administration of other anti-inflammatory drugs, such as methotrexate and anti-vascular endothelial growth factors (anti-VEGF) agents have also been shown, in a small case series, as being a potential alternative treatment for refractory uveitic CME.<sup>37,38</sup> However, although these agents have a rapid effect in reducing the macular edema and in improving the visual acuity, their action is also short-lived and repeated injections may be required. Their long-term effects are also unknown, and there is concern that repeated injections of the anti-VEGF agents themselves may be associated with the occurrence of uveitis.<sup>39</sup> Somatostatin analogues, such as octreotide, IFN- $\alpha$  drugs, and long-term low-dose acetazolamide, are other potential modalities for management of CME secondary to IU.<sup>40–42</sup> Infliximab has been reported to improve CME in patients who have uveitis but no other demonstrable features of inflammation.<sup>43</sup>

## Surgical Management

Pars plana vitrectomy in addition to its role in management of the complications of IU, such as CME, ERM, retinal detachment, or vitreous hemorrhage, has also been advocated as an alternative to immunosuppressants for the control of active inflammation. By removing inflammatory cells and membranes, it has been found to be useful in reducing visual loss from CME and ERM, as well as in reducing the requirement for immunosuppressive therapy.<sup>44–46</sup>

Cataract surgery should be undertaken when the eye has been quiet for at least 3 months; with meticulous surgery as well as perioperative immunosuppressants or intravitreal corticosteroids, as indicated, at least 79% majority of patients improve by  $\geq 2$  Snellen lines. The main causes of poor vision are posterior capsule opacification, CME, ERM, and submacular fibrosis.<sup>47</sup>

## PROGNOSIS

The prognosis for most patients with IU is generally good. The mean visual acuity after 10 years of follow-up was 20/30, with 75% achieving 20/40 or better visual acuity<sup>5,20</sup> and remission was seen in 30%–50% of patients, with younger age being associated with a better outcome.<sup>8,19,21</sup> However, children age  $< 7$  years had a less favorable outcome, with poorer vision requiring longer treatment, a lower likelihood of remission, and a higher probability of secondary glaucoma, vitreous hemorrhage, and need for cataract surgery.<sup>21</sup>

# Posterior Uveitis of Unknown Cause— White Spot Syndromes

7.22

Rukhsana G. Mirza, Ramana S. Moorthy, Lee M. Jampol

**Definition:** A heterogeneous group of posterior segment inflammatory disorders of unknown cause involving the outer retina, retinal pigment epithelium, choroid, or a combination of these in one or both eyes of patients in their second to sixth decades of life.

## Key Feature

- Multiple unilateral or bilateral discrete outer retinal or choroid inflammatory lesions that appear white or placoid.

## Associated Features

- Unilateral or bilateral, depending on the disease.
- Second to sixth decades of life.
- Often female predilection.
- Variable inflammatory cells in the anterior chamber and vitreous humor, depending on the disease.
- Usually self-limiting course, but variable prognosis, depending on the disease.
- Unknown cause with negative serological evaluation.

## INTRODUCTION

White spot syndromes (WSSs) are a group of diseases that affect the outer retina, retinal pigment epithelium (RPE), choroid, or a combination of these. The lesions are typically multifocal in nature. They may present in one eye or both eyes. When bilateral, they may be asymmetrical. The white spots themselves may be a variable finding. For this reason, the term *inflammatory multifocal chorioretinopathies* may be more appropriate.

Patients in the second to sixth decades of life are typically affected by these diseases. The entities covered in this chapter include birdshot chorioretinopathy (BCR), acute posterior multifocal placoid pigment epitheliopathy (APMPPE), serpiginous choroiditis (SC), relentless placoid chorioretinitis (RPC), persistent placoid maculopathy (PPM), idiopathic multifocal choroiditis (MFC)/punctate inner choroidopathy (PIC), multiple evanescent white dot syndrome (MEWDS), acute zonal occult outer retinopathy (AZOOR), and acute macular neuroretinopathy (AMN). These diseases present in a varied fashion; however, there are some similarities. Many have a female predilection. Some common presentations include blurred vision; photopsias; visual field changes, including an enlarged blind spot; and floaters. These diseases are thought to be inflammatory in nature, but iritis and vitritis are not essential findings in the diagnosis of most of these entities. These syndromes have no known cause. An autoimmune etiology has been hypothesized,<sup>1</sup> and it appears that this group of diseases occurs in families with inherited immune dysregulation that predisposes to autoimmunity.<sup>2</sup> Although some of these disorders are self-limiting and have good visual outcomes, others are associated with serious retinal and choroidal sequelae and can result in visual loss. Newer imaging modalities, such as spectral-domain optical coherence tomography (SD-OCT) and enhanced depth imaging optical coherence tomography (EDI-OCT), fundus autofluorescence (FAF), and optical coherence tomography angiography (OCTA), are shedding light on the pathogenesis and prognosis of these syndromes. Multimodal imaging now can distinguish

what were previously thought to be overlapping diseases. Acute idiopathic blind spot enlargement (AIBSE), initially described by Fletcher et al. in 1988,<sup>3</sup> has, in the past, been presented as a distinct entity within WSS. Many of the cases that were described in the literature can now be identified as “other WSS,” and we believe that an enlarged blind spot may be a feature of these “other” diseases, rather than being its own clinical entity.

## BIRDSHOT CHORIORETINOPATHY

### Epidemiology and Pathogenesis

Birdshot chorioretinopathy (BCR) also has been called *birdshot retinochoroidopathy*<sup>4</sup> and *vitiliginous chorioretinitis*.<sup>5</sup> The preferred term *BCR* is used here because of histopathological evidence that the primary lesions of the disease are located in the choroid.<sup>6</sup> This syndrome affects healthy patients, usually women, between the third and sixth decades of life.<sup>4,6</sup> At least 90% of patients who have BCR possess the human lymphocyte antigen A\*29 (HLA-A\*29) allele compared with 7% of the general Caucasian population. Subtype HLA-A29.2 occurs most commonly in Caucasians with BCR.<sup>7</sup> This is the highest association of any HLA antigen with a human disease.

### Ocular Manifestations

Patients complain of blurred vision, floaters, central and peripheral photopsias, and, later, nyctalopia and color blindness.<sup>4-6</sup> The lesions of BCR are scattered around the optic disc and radiate to the equator in a “shotgun” pattern; they sometimes appear to follow choroidal vessels (Fig. 7.22.1). The creamy lesions are small and <1 disc diameter in size. They can be oval or round in shape and are located deep to the retina. They tend to cluster near the nerve, especially nasal and inferiorly to it.<sup>8</sup> Vitreous inflammation is present. Disc edema, narrowed retinal vessels, and cystoid macular edema (CME) are also seen.

**Fig. 7.22.1 Birdshot Chorioretinopathy.** Note the optic disc edema, vitritis, and multiple, creamy, yellow choroidal lesions in the midperiphery of the left eye.

## Diagnosis

The diagnosis of BCR can be made on the basis of history and physical findings. However, imaging is useful to delineate the disease and monitor therapy. Fluorescein angiography (FA) reveals disc staining, vascular leakage, and, often, late CME.<sup>5,6</sup> The birdshot lesions have variable appearance with this mode of imaging and generally are seen better clinically. In the late phases of angiography, these hypopigmented lesions can appear mildly hyperfluorescent. Indocyanine green angiography (ICGA) in acute disease demonstrates hypofluorescent lesions in the intermediate phase of the angiography, and the lesions are bordered by medium-to-large vessels even before apparent clinical lesions.<sup>9</sup> SD-OCT demonstrates circular patches of chorioretinal atrophy, ellipsoid zone disruption, outer retinal atrophy,<sup>10</sup> and chronic retinal thinning.<sup>11</sup> EDI-OCT shows reduction in choroidal thickness and volume with increased disease duration.<sup>12</sup> SD-OCT is also useful in monitoring CME, a common cause of vision loss in BCR.<sup>11</sup> OCTA demonstrates retinal capillary density reduction at the deep retinal capillary plexus level and may explain the development of retinal neovascularization (NV), retinal thinning, and reduction of visual function.<sup>13</sup> FAF<sup>14,15</sup> reveals more extensive hypoautofluorescent lesions than are seen clinically. In addition, perivascular linear and late macular hypoautofluorescent patterns are noted on FAF.<sup>16</sup> Electroretinography (ERG) is important in the diagnosis and management of BCR. It may show moderately to severely depressed rod and cone function. Severe cases often demonstrate an extinguished image on ERG. Results of electro-oculography (EOG) usually are normal but can be variably subnormal in some patients.<sup>5,17,18</sup> Visual field abnormalities are common in BCR. These can include peripheral constriction, enlarged blind spot, central or paracentral scotomas, and generalized diminished sensitivity.<sup>5,8</sup> Visual field testing is important in monitoring BCR.

## Differential Diagnosis

The differential diagnosis of BCR is given in [Box 7.22.1](#). Several disorders produce multiple, creamy choroidal lesions. Not many are as commonly associated with CME as is BCR. Pars planitis and chronic iridocyclitis can produce CME but are not associated with choroidal lesions. Onset of vitritis and CME in the fifth and sixth decades is characteristic of BCR. Sarcoidosis and BCR may be the most difficult to distinguish from each other.<sup>6</sup> Unilateral birdshot-type lesions with or without vitritis can be seen in newly described diseases, such as benign reactive lymphoid hyperplasia, indolent nonprogressive multifocal lesions,<sup>19</sup> and frank lymphoid tumors.

## Treatment

Photoreceptor loss is an important component of vision loss. Macular edema caused by inflammation is another reason for vision loss. Optic disc edema leading to atrophy can also be vision threatening. Corticosteroids have been the short-term mainstay of therapy for patients who have BCR. Oral, sub-Tenon's, intraocular, and the most recently described sustained-release administrations of fluocinolone acetonide<sup>20</sup> have been used. Corticosteroids carry their own systemic and local (glaucoma and cataract) risks. Therefore, corticosteroid-sparing immunomodulatory agents have been used in the long-term management of refractory cases. Systemic cyclosporine, azathioprine, mycophenolate mofetil, or low-dose methotrexate may be administered (sometimes in combination) judiciously, if necessary with the help of an oncologist, a rheumatologist, or an internist. With

the approval of the US Food and Drug Administration (FDA) for adalimumab for noninfectious posterior uveitis, second-line immunomodulatory therapy with this tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) inhibitor can also be used when first-line agents fail. Choroidal neovascularization (CNV) is rare in BCR, but anti-vascular endothelial growth factor (VEGF) therapy has been demonstrated to be useful in treatment of CNV associated with inflammatory chorioretinal disorders.<sup>21</sup> In managing BCR, close monitoring of visual acuity, Goldmann visual fields at least yearly, ERG yearly, and OCT to evaluate for integrity of photoreceptors, epiretinal membranes (ERMs), and CME are recommended.

## Course and Outcome

The long-term visual prognosis for patients with BCR is guarded. The disease is chronic and does not appear to undergo regression. Retinal vascular attenuation and chorioretinal atrophy may eventually occur. Evidence suggests that patients treated with corticosteroid-sparing immunomodulatory agents experience stabilization or, at least, deceleration of clinical and electrophysiological disease progression.<sup>17,18</sup> Chronic CME may cause permanent visual loss.<sup>6</sup>

## ACUTE POSTERIOR MULTIFOCAL PLACOID PIGMENT EPITHELIOPATHY

### Epidemiology and Pathogenesis

APMPPE is a bilateral inflammatory disease that affects the choriocapillaris, RPE, and outer retina of otherwise healthy young adults, often in the second and third decades of life. Men and women are affected equally. The disease may be preceded by a viral prodrome.<sup>22</sup>

### Ocular Manifestations

Patients develop sudden, painless loss of vision in one eye or, more typically, both eyes.<sup>22</sup> Symptoms of mild meningismus, headaches, and transient hearing loss have been reported.<sup>23–25</sup> Cerebral vasculitis can occur. Ocular examination usually shows no evidence of anterior uveitis. Minimal to no vitreous cells occur.<sup>22,26</sup> Multiple, yellow, creamy-colored, flat-to-placoid (plate-like) lesions of variable size are seen and involve the posterior pole ([Fig. 7.22.2](#)).<sup>22,26</sup> In general, these lesions do not occur anterior to the equator. Fresh lesions may present over the course of a few weeks, so lesions of differing ages can be seen. These lesions can be associated with exudative detachments.<sup>24,27–32</sup> As the lesions resolve, they tend to clear centrally and they become hypopigmented. Later pigment clumping occurs. An association with retinal vasculitis and retinal vein occlusions has been reported.<sup>33,34</sup> CNV is rare.<sup>35</sup> Optic disc edema has also been noted in APMPPE.<sup>36</sup>

**Fig. 7.22.2 Fundus View of the Right Eye of a 17-Year-Old Man With Acute Posterior Multifocal Placoid Pigment Epitheliopathy.** Numerous creamy, white-yellow, placoid lesions are seen in the posterior pole. Note the pigmented lesion in the inferior macula that has started to heal.

### BOX 7.22.1 Differential Diagnoses in Birdshot Chorioretinopathy

- Pars planitis
- Sarcoidosis
- Chronic iridocyclitis, idiopathic
- Papilledema
- Intraocular lymphoma
- Vogt-Koyanagi-Harada syndrome
- Multifocal choroiditis
- Ocular histoplasmosis syndrome
- Syphilis
- Sympathetic uveitis
- Indolent nonprogressive multifocal choroidal lesions
- Metastasis

**Fig. 7.22.3 Hypofluorescence of Acute Lesions and Early Hyperfluorescence of Healing Lesions.** Laminar, venous-phase fluorescein angiography image of the right eye of the patient shown in Fig. 7.22.2.

**Fig. 7.22.4 Late Hyperfluorescence of Both Acute and Healing Lesions.** Late arteriovenous-phase fluorescein angiography image of the same eye as shown in Figs. 7.22.2 and 7.22.3.

## Diagnosis

APMPPE is diagnosed on the basis of clinical examination findings, time course, and imaging characteristics. The absence of substantial anterior chamber or vitreous inflammation in a young, healthy patient who has a viral prodrome with placoid fundus lesions is highly suggestive of APMPPE. FA shows early hypofluorescence of these white placoid lesions with late staining of these same lesions (Figs. 7.22.3 and 7.22.4).<sup>22</sup> ICGA shows hypofluorescent lesions in the acute phase of the disease. These areas are more numerous than the clinically seen plaques. OCTA definitively demonstrates patchy areas of choriocapillaris ischemia corresponding to the clinical lesions that improve to varying degrees with disease regression.<sup>37–39</sup> These findings confirm that the pathogenesis of APMPPE can, at least partially, be attributed to ischemia of the choriocapillaris.<sup>37</sup> OCT shows disruption of the external limiting membrane (ELM), inner segment/outer segment (IS/OS) junctions, and the ellipsoid zone in the outer retina, with areas of hyperreflectivity in the photoreceptor layer corresponding to the placoid lesions.<sup>40,41</sup> RPE disruption, restoration of the ELM, and increase in photoreceptor volume occur as the lesions begin to heal.<sup>40</sup> In our experience, the outer retinal elements can regenerate in this disease, likely signifying an improved prognosis in these patients.<sup>40</sup> FAF is useful in delimiting RPE involvement in this disease.<sup>42</sup> Laboratory

### BOX 7.22.2 Differential Diagnoses in Acute Posterior Multifocal Placoid Pigment Epitheliopathy

Serpiginous choroidopathy  
Relentless placoid chorioretinitis  
Persistent placoid maculopathy  
Choroidal vasculitis (lupus, polyarteritis nodosa)  
Syphilitic retinitis  
Harada's disease  
Tuberculosis, sarcoid, fungal disease  
Outer retinal toxoplasmosis  
Viral or bacterial retinitis  
Choroidal metastasis  
Lymphoma

evaluation of these patients is usually unrewarding (except for the findings of protein and cells in cerebrospinal fluid [CSF], and rare hematuria) and usually not necessary. Cerebral involvement should dictate neurological consultation because deaths resulting from this have been reported.

## Differential Diagnosis

The differential diagnoses of APMPPE are listed in Box 7.22.2. Primarily, other white spot diseases should be considered. Specifically, SC should be considered in recurrent/chronic cases and RPC should be thought of in severe, persistent, and recurrent cases. The creamy lesions of APMPPE are unique but occasionally may be confused with Harada's disease, metastatic tumors, viral retinitis, syphilis, and toxoplasma retinochoroiditis. In APMPPE, however, the creamy lesions are flat and are not associated with significant vitritis. Healed APMPPE usually leaves behind variable pigmentary changes in the posterior pole. The scars may be difficult to differentiate from other inactive inflammatory conditions. Failure to show healing with concomitant RPE changes is suggestive of an alternative diagnosis, such as RPC or lymphoma.

## Systemic Associations

Cerebral vasculitis and CSF pleocytosis have been reported in patients who have APMPPE.<sup>23–26</sup> Rarely, this may be fatal. Acute nephritis occurred concurrently with APMPPE in one patient.<sup>43</sup> Serological evidence of mumps<sup>44</sup> and adenovirus type 5 infection has been documented.<sup>45</sup>

## Pathology

The etiology and the histopathology are unknown. Various theories exist. Some authors believe that a vascular insult involving the choroid possibly leads to some choroidal ischemia causing RPE damage and thus affects photoreceptors. However, it is also possible that the primary site of inflammation is in the outer retina and that this affects the choroid. It is likely that some trigger, either inflammatory or infectious, incites this process. In addition, some individuals may be more prone to this insult.<sup>46</sup> Delayed-type hypersensitivity<sup>47</sup> and a thrombotic process of the choroid have also been postulated.<sup>48</sup>

## Treatment

Usually, no treatment is necessary; the disease is self-limiting. Some ophthalmologists use systemic corticosteroids, although there is no definitive evidence that corticosteroids speed visual recovery or improve the visual outcome.<sup>49</sup> Rarely, CNV can develop. Anti-VEGF agents have been found useful.<sup>21</sup>

## Course and Outcomes

In most patients, APMPPE runs a self-limiting course of 2–6 weeks. Visual acuity is usually diminished during the early part of the disease and may vary from 20/20 (6/6) to 20/400 (6/120), depending on the location of the placoid lesions. In most patients, vision improves to near-normal levels during the first 2–3 weeks after the onset of symptoms. Patients, however, may continue to complain of difficulty with reading or of scotomas in the central visual field. The placoid lesions resolve over a period of 2–6 weeks. Significant macular RPE mottling and alterations remain after the resolution of these placoid lesions.<sup>22</sup> There are reported cases of

**Fig. 7.22.5 Fundus View of the Right Eye of a 57-Year-Old Woman With Early Serpiginous Choroiditis.** A peripapillary serpentine lesion extends into the fovea. Visual acuity is 20/60 (6/18).

persistent, chronic, or recurrent APMPE in which severe RPE alterations may occur.<sup>50</sup> This can result in severe vision loss. Recurrent cases must be distinguished from SC. Chronic cases probably represent RPC. CNV is an uncommon complication of APMPE but has been reported.<sup>51</sup> Permanent disruption of Bruch's membrane and the choriocapillaris occurs less frequently in APMPE than with SC.

## SERPIGINOUS CHOROIDITIS

### Epidemiology

SC has also been called *helicoid peripapillary chorioretinal degeneration*, *geographical helicoid peripapillary choroidopathy*, and *geographical choroidopathy*. Our current understanding of this rare disease is limited. The condition affects healthy patients from the second to seventh decades of life. Men and women are affected equally.<sup>52</sup> It is usually bilateral, recurrent, and progressive. This disease affects the outer retina and RPE, perhaps associated with impaired circulation in choriocapillaris and inner choroid.<sup>53–55</sup>

### Ocular Manifestations

Although a bilateral disease, the patient usually presents with unilateral symptoms when a lesion affects the fovea. Patients may experience paracentral or central scotomata with vision loss. Ocular examination may reveal some inflammatory response in the anterior chamber or vitreous humor.<sup>56</sup> Serpiginous lesions are geographical gray or gray-yellow areas that begin either in the peripapillary region or macula and eventually affect both eyes. Unlike in APMPE, usually one eye is active at a time, with one or a few foci. New lesions usually appear at the edges of healed scars. The disease has a progressive, stepwise course. Often, these lesions progress in a centripetal, helicoid, or serpentine-like fashion from the peripapillary area or macula into the remainder of the posterior pole (Fig. 7.22.5).<sup>52,57</sup> With time, these lesions become atrophic, with disappearance of the RPE, choriocapillaris, and choroid.<sup>53</sup> In patients who have macular SC, the initial lesions are seen in the macula.<sup>58</sup> Subretinal hemorrhage and serous retinal detachment as a result of CNV can occur in eyes with SC.<sup>59</sup>

### Diagnosis

Diagnosis is established on the basis of typical clinical appearance. FA demonstrates early hypofluorescence and late hyperfluorescence of active lesions. ICGA also shows hypofluorescent active and healed lesions. Atrophic lesions show diffuse loss of pigment, choroidal vessels, and late staining on FA. Retinal vascular staining may occur adjacent to active lesions. Associated CNV shows late leakage and often arises from the borders of old scars.<sup>59</sup> The individual lesions may resemble APMPE and RPC, but the clinical setting and course distinguish these diseases in most patients. SD-OCT has shown hyperreflective outer retina, with disruption of ellipsoid zone in acute lesions and eventual retinal thinning and RPE atrophy with resolution.<sup>60,61</sup> OCTA demonstrates multiple small geographical areas of inner choroidal/choriocapillaris nonperfusion within active lesions that improve with treatment.<sup>62</sup> Older atrophic lesions are marked by decreased

### BOX 7.22.3 Differential Diagnoses in Serpiginous Choroiditis

Acute multifocal placoid pigment epitheliopathy  
Relentless placoid chorioretinitis  
Persistent placoid maculopathy  
Birdshot choroidopathy  
Multifocal choroiditis  
Presumed ocular histoplasmosis  
Tuberculous (serpiginous) choroiditis  
Sarcoidosis  
Antiphospholipid antibody syndrome  
Toxoplasmosis  
Syphilis  
Posterior scleritis  
Choroidal ischemia (vascular diseases, such as systemic lupus erythematosus, polyarteritis nodosa, toxemia of pregnancy, disseminated intravascular coagulopathy, thrombotic thrombocytopenic purpura, and malignant hypertension)

or absent inner choroidal vessels.<sup>54</sup> FAF has been effective in illustrating new lesions as hyperautofluorescent, appearing at the edge of old lesions, which are hypoautofluorescent.<sup>63</sup> Furthermore, FAF seems to be useful in distinguishing tuberculosis (TB)-related disease from SC. TB lesions that mimic SC appear more stippled compared with the more homogeneous lesions of SC.<sup>63</sup>

Laboratory evaluation of these patients is unrevealing. An association of serpiginous choroiditis and TB has been suggested. However, treatment of patients without TB with antimicrobial agents has made no difference in the disease course in these patients.<sup>53</sup>

### Differential Diagnosis

The differential diagnoses for SC are listed in Box 7.22.3. Other white spot syndromes, especially APMPE, RPC, and PPM should be considered. The peripapillary scarring seen in SC may be difficult to differentiate from inactive MFC and ocular histoplasmosis syndrome. However, serpentine centripetal progression and chronic, relapsing time course are characteristic of SC. Tuberculous SC can also resemble SC; however, it is associated with more vitritis and more multifocal lesions involving the periphery. SC has larger lesions and is more likely to be associated with the optic nerve.<sup>64</sup>

### Pathology

The few eyes with SC studied histopathologically showed extensive loss of RPE, with destruction of the overlying retina and lymphocytic infiltration of the choriocapillaris and other areas of the choroid.<sup>53</sup> The pathogenesis remains unknown. Autoimmune, infectious, vascular, and degenerative etiologies have been postulated.

### Treatment

Because of the relapsing and progressive nature of this disease, therapy is aimed at treating acute episodes as well as at preventing recurrences that can lead to foveal involvement. Corticosteroids are a mainstay of treatment and have been given via multiple routes of administration (oral, sub-Tenon's, intravenous, intravitreal injections and via an implant). Aggressive management with corticosteroids is useful in treating acute attacks but not in preventing recurrence. Treatment with other immunosuppressive therapy may be necessary for long-term management of SC. Cyclosporine, azathioprine, and other cytotoxic agents have been used to treat SC.<sup>53</sup> Because these medications have associated potential systemic side effects, they should be used in consultation with a rheumatologist, an internist, or an oncologist. In addition, systemic TNF- $\alpha$  inhibitors, such as adalimumab, may be used in relentless or recalcitrant cases in conjunction with the previously mentioned corticosteroid-sparing immunomodulatory agents. However, these agents should be used only after tuberculous SC has definitively been ruled out because these agents are contraindicated in latent or active TB. CNV is common in this disease, and there are reports of response to anti-VEGF injection.<sup>21</sup> CME can develop in SC, and treatment success has been reported with the use of oral acetazolamide.<sup>65</sup>

## Course and Outcomes

Many cases of SC are progressive, and foveal destruction may occur. Central visual acuity is lost in  $\geq 20\%$  of eyes with SC.<sup>53</sup> Central vision loss also can occur as a result of CNV. Long-term immunosuppressive therapy may prevent vision loss.<sup>66</sup>

## RELENTLESS PLACOID CHORIORETINITIS

### Epidemiology

RPC is a rare, often bilateral ocular inflammatory disease of unknown etiology affecting patients between the second and sixth decades of life.<sup>67</sup> This disease resembles both APMPE and SC but is distinguished by its time course and retinal distribution. The term *ampiginous* has been used to describe similar cases. Men and women are equally affected in RPC. When seeking treatment, patients complain of decreased vision, pericentral scotomas, photopsias, floaters, and, rarely, pain.

### Ocular Manifestations

Varying numbers of anterior chamber and vitreous cells may be seen. Active retinal lesions are creamy white and located at the level of the outer retina. They may be smaller than those of APMPE ( $\frac{1}{2}$  disc area). The lesions can be active bilaterally and may affect the mid- and far periphery prior to involvement of the posterior pole, unlike APMPE or SC.<sup>67</sup> Many of these lesions heal over weeks, resulting in chorioretinal atrophy. However, progressive increase in size of subacute lesions and development of new lesions occurs in all patients. The hallmark of the disease is the eventual presence of  $\geq 50$  lesions can occur throughout the fundus. These lesions eventually can involve the macular region and acutely result in visual loss, metamorphopsia, or scotoma. Subretinal fluid may be seen in association with the acute lesions. When these lesions heal, visual acuity is often preserved even with macular involvement.<sup>67</sup>

### Diagnosis

Diagnosis is based on clinical appearance of retinal lesions and prolonged clinical course, unless shortened by immunosuppression. APMPE and SC are the main considerations. FA show early hypofluorescence and late staining of lesions as in APMPE and SC. Similarly, ICGA shows hypofluorescence in the areas corresponding to the clinical lesions. SD-OCT demonstrates retinal photoreceptor disruption in the ellipsoid zone surrounding the areas of central subretinal fluid in early lesions and RPE atrophy with patchy hyperplasia and rarefaction of the ellipsoid zone as lesions heal.<sup>68</sup> OCTA demonstrates multifocal areas of inner choroidal ischemia, which improve with treatment but recur in adjacent and noncontiguous areas.<sup>37</sup> FAF of early lesions demonstrate three concentric zones with a central round area of dense hypoautofluorescence, surrounded by a narrow ring of hyperautofluorescence, which, in turn, is surrounded by a faint wider ring of hypoautofluorescence.<sup>68</sup> Over time, these lesions contract on FAF and become more hyperautofluorescent with central hypoautofluorescent RPE hyperplasia. Laboratory evaluation is not helpful. No consistent systemic association has been found.

### Differential Diagnosis

See Box 7.22.4.

#### BOX 7.22.4 Differential Diagnoses in Relentless Placoid Chorioretinitis

Acute posterior multifocal placoid pigment epitheliopathy  
Serpiginous choroiditis  
Persistent placoid maculopathy  
Multifocal choroiditis  
Viral retinitis  
Choroidal vasculitis (e.g., systemic lupus erythematosus, polyarteritis nodosa)  
Neoplastic infiltration of the choroid  
Syphilis  
Sarcoid  
Tuberculosis

## Treatment

In the original report on RPC, glucocorticoids, antiviral agents, and cyclosporine all were tried to treat patients. Immunosuppression did appear to halt disease activity.<sup>67</sup> With glucocorticoid treatment, healing and improvement in visual acuity are observed; however, the disease can recur despite the use of glucocorticoids. Corticosteroids have been used in combination with azathioprine or cyclophosphamide as well.<sup>69</sup> The best treatment for this condition remains unknown.

### Course and Prognosis

Growth of subacute lesions and appearance of new lesions occurs from 5–24 months after initial diagnosis. Relapses are common. Eventually, most patients develop  $\geq 50$  (sometimes hundreds) of healed lesions in the periphery and posterior pole. The long-term visual prognosis appears to be good.<sup>67</sup> Central vision is generally preserved. Intensive immunosuppression may shorten the course of the disease, but relapses occur on tapering of medication.

## PERSISTENT PLACOID MACULOPATHY

### Epidemiology and Pathogenesis

PPM is a recently recognized, bilateral, symmetrical entity primarily affecting patients in the sixth and seventh decades of life.<sup>70,71</sup> The etiology is unknown, and no consistent systemic associations have been found.

### Ocular Manifestations

Patients report decreased vision and photopsias in both eyes. All patients demonstrate a well-delineated, jigsaw-patterned, whitish, plaque-like lesion involving the fovea and not contiguous with the disc. Satellite lesions may be seen. PPM resembles macular SC. Although the fovea is involved in PPM, vision may be remarkably good (20/25–20/50). The whitish lesion persists in the macula for months and may be replaced by pigment mottling or atrophy. Many patients develop CNV within months to years that may be multifocal, with severe vision loss resulting from disciform scarring.<sup>70</sup>

FA demonstrates early hypofluorescence of the macular lesions with partial filling in the late phases. There is no leakage unless CNV is present. ICGA demonstrates persistent hypofluorescence of macular lesions throughout the study, with visible large choroidal vessels observed within the lesions.<sup>70</sup> SD-OCT shows hyporeflectivity of the outer retina and ellipsoid zone disruption early,<sup>72,73</sup> with variable loss of the outer retina in long-standing disease.<sup>73</sup> OCTA demonstrates hypoperfusion of the choriocapillaris that persists, although with some improvement, despite treatment.<sup>37,72</sup> FAF may show stippled hyperautofluorescence early and hypoautofluorescence correlating to RPE damage in the later stages.<sup>71</sup>

### Differential Diagnosis

The differential diagnosis includes macular SC, APMPE, RPC, syphilitic placoid chorioretinitis, and diseases that cause choroidal ischemia (e.g., systemic lupus erythematosus, polyarteritis nodosa, disseminated vascular coagulopathy, thrombotic thrombocytopenic purpura, and malignant hypertension). CNV occurs less frequently in macular SC than in PPM. Syphilitic placoid chorioretinitis is generally associated with clinical signs of inflammation as a result of the infectious etiology (Box 7.22.5).

#### BOX 7.22.5 Differential Diagnoses in Persistent Placoid Maculopathy

- Macular Serpiginous Choroiditis
- Acute posterior multifocal placoid pigment epitheliopathy
- Relentless placoid chorioretinitis
- Syphilis
- Diseases that cause choroidal ischemia
  - Systemic lupus erythematosus
  - Polyarteritis nodosa
  - Disseminated intravascular coagulopathy
  - Thrombotic thrombocytopenic purpura
  - Malignant hypertension

## Treatment

Oral corticosteroids may be of some benefit in the acute phase of the disease to improve initial visual loss but do not prevent the eventual development of CNV and disciform scarring. CNV has been treated with anti-VEGF agents, with good results, as described in a report.<sup>74</sup> Reports have suggested that photodynamic therapy (PDT) has not been of benefit.

## Course and Outcome

Patients may retain good vision despite the entire macula being involved with a white lesion for months to years. The long-term prognosis, however, is sometimes poor because many patients eventually develop subfoveal CNV and lose central vision. Some eyes lose vision to pigmentary degeneration, atrophy, and mottling.

## MULTIFOCAL CHOROIDITIS/PUNCTATE INNER CHOROIDOPATHY

MFC and PIC are considered the same entity by many retina specialists and have been classified as the same disease process by Jampol et al.<sup>75,76</sup> Multimodal imaging has supported this classification.<sup>75,77,78</sup> Historically, the term *PIC* was used when lesions were limited to the posterior pole, and *MFC* was used when lesions extended to the periphery as well. Some lesions also have significant fibrosis associated with them. The term *subretinal fibrosis and uveitis syndrome* has been used in the past<sup>79</sup> when significant fibrosis was present. We consider fibrosis as a feature of the same disease and not a separate entity. In this chapter, the term MFC/PIC or MFC will be used. It should further be clarified that the MFC discussed in this chapter is the idiopathic type. MFC can be secondary to other processes, including infectious (TB, syphilis, fungal/presumed ocular histoplasmosis syndrome [POHS], viral infections) and noninfectious etiologies (sarcoidosis).

## Epidemiology

MFC along with PIC is a common inflammatory disease that occurs predominantly in women with myopia between their second and sixth decades of life. Most cases are bilateral when diagnosed or become bilateral.<sup>80,82</sup> MFC and PIC are characterized by inflammation at the level of the RPE and outer retina, so “choroiditis” may be a misnomer.

## Ocular Manifestations

Patients present with decreased visual acuity in one eye or both eyes. Photopsias may be present (often temporal), and patients may be symptomatic with an enlarged blind spot. There is a variable amount of anterior segment inflammation and vitritis; however, this is not essential to diagnosis. When there is a significant amount of vitritis, the term *multifocal choroiditis and panuveitis* has been used. These patients are commonly seen by uveitis specialists, but we consider these part of the spectrum of the same disease. The optic discs generally are normal, but the peripapillary RPE often is disrupted. An area of fibrosis in the shape of a “napkin ring” may surround the disc. Acute lesions are yellowish to gray in color and located at the level of the RPE and outer retina; they range in size from 50 to 1000 microns. Serous detachment of the retina may accompany active lesions. The lesions may vary in number from several to hundreds. They occur in the posterior pole, peripapillary region, and midperiphery with often a clustering in the nasal retina. They can occur in linear clusters or as streak lesions.<sup>83</sup> Older lesions appear atrophic and “punched out,” with variable amounts of pigment. RPE metaplasia with associated fibrosis may be seen, and this fibrosis can bridge the space between scars (Fig. 7.22.6).<sup>80</sup> Some cases show evanescent white lesions resembling MEWDS. Those can resolve without scarring. Peripapillary and macular CNV occurs in more than one third of eyes.<sup>81</sup> CNV may occur in up to 70% of eyes from healed scars. If CNV occurs in the macula or near the fovea, serious vision loss may result.<sup>84,85</sup> CNV may be the presenting sign of disease. MFC may also present with more diffuse photoreceptor loss distinct from focal lesions,<sup>86</sup> which we have described as MFC with chorioretinal atrophy.<sup>87</sup> The chorioretinal atrophy can be diffuse, multizonal, or zonal.<sup>86</sup> Previously, these cases may have been classified in the past as being part of Gass’s AZOOR complex<sup>88</sup> but now can be distinguished by using multimodal imaging.

**Fig. 7.22.6 Punctate Inner Choroidopathy.** White, punctate chorioretinal lesions in the macula with overlying serous retinal detachment of the fovea in the right eye of a 20-year-old woman with myopia. (Courtesy Richard R. Ober.)

## Diagnosis

Diagnosis is made on the basis of clinical examination findings, although imaging is helpful. In the acute stage, the lesions appear hypofluorescent on FA. Later, these lesions stain. In the healed phase, the lesions atrophy and show a window defect. Peripapillary or subfoveal CNV may be seen. CME may be seen in the late phases of angiography in some patients.<sup>80</sup> ICGA shows hypofluorescent lesions that may cluster around the optic disc; these lesions often are far more numerous than those seen on FA or clinical examination. SD-OCT shows an elevation of the RPE corresponding to active lesion with loss of the ellipsoid layer, outer photoreceptor damage, choroidal thickening, and subretinal material that may erupt through the RPE with an intact Bruch’s membrane.<sup>89</sup> This can potentially normalize with treatment, or there can be persistent outer retinal atrophy. OCTA has been somewhat useful in distinguishing inflammatory lesions from CNV.<sup>90–92</sup> FAF can show diffuse zone of peripapillary and/or multiple posterior-pole hyperautofluorescent acute lesions, even in areas that appear clinically uninvolved, and that can resolve with treatment.<sup>89,93</sup> In our experience, numerous hypoautofluorescent lesions not associated with clinical lesions have been seen, and these also resolved in the healing phase.<sup>94</sup> Punched-out lesions appear hypoautofluorescent persistently and may enlarge with time. ERG results are usually normal, or mildly attenuation is seen; however, in severe cases, it may be extinguished. The EOG result is normal.<sup>80</sup> Visual field testing may reveal an enlarged blind spot and, rarely, other abnormalities. Evanescent white spots may be seen, but these may resolve with or without treatment and with or without scarring. These can resemble MEWDS.

## Systemic Associations

An association between MFC and systemic infection by Epstein–Barr virus has been suggested.<sup>95</sup> A second investigation could not confirm this. Some patients who have MFC also have known sarcoidosis or are diagnosed later with sarcoidosis. These cases may be indistinguishable from the group with idiopathic etiology. Often, the sarcoid lesions predominate in the inferior retina.

## Course and Outcomes

MFC waxes and wanes, but progressive loss of vision may take place. Episodes can resolve spontaneously or with the help of immunosuppressants. In ≈25% of cases, the disease takes a more aggressive course, with more inflammation and CNV. CNV is the most common cause of vision loss.<sup>85,96</sup> Macular disciform scarring may develop. Severe cases of subretinal fibrosis may develop (Fig. 7.22.7).<sup>80,81</sup> Loss of photoreceptors with more widespread

**Fig. 7.22.7** Fundus View of the Right Eye of a Patient Who Has Progressive Subretinal Fibrosis and Uveitis Syndrome. Note the extensive submacular fibrosis.

#### BOX 7.22.6 Differential Diagnoses in Multifocal Choroiditis /Punctate Inner Choroidopathy

- Multiple evanescent white dot syndrome
- Presumed ocular histoplasmosis syndrome
- Sarcoidosis
- Vogt–Koyanagi–Harada syndrome
- Sympathetic ophthalmia
- Myopic degeneration maculopathy
- Serpiginous choroiditis
- Infectious etiologies: viral (herpes simplex virus, herpes zoster virus, Epstein–Barr virus, cytomegalovirus, Coxsackievirus)
  - Bacterial (syphilis, tuberculosis, *Borrelia burgdorferi* infection, septic choroiditis, metastatic endophthalmitis)
  - Fungal (histoplasmosis, cryptococcosis, coccidiomycosis, candidiasis)
  - Protozoal (toxoplasmosis, *Pneumocystis carinii* infection)
  - Helminthic (diffuse unilateral subacute neuroretinitis)
- Neoplastic: intraocular lymphoma

chorioretinal atrophy may be seen. ERMs and CME are other causes of vision loss.<sup>96</sup>

### Differential Diagnosis

The differential diagnoses for MFC/ PIC are listed in Box 7.22.6. Evanescent lesions may resemble MEWDS. MFC and POHS have many similarities in their punched-out lesions involving the posterior pole as well as the periphery. Additionally, peripapillary changes and CNV can be seen in both these entities. Classically, MFC has some degree of intraocular inflammation, but this is not necessary. Clinically distinct features of MFC include multiple, small, white lesions that cluster in the macula, nasal retina, or equator. Furthermore, the presence of acute and inactive lesions, growth of lesions, subretinal fibrous metaplasia, and bridging tissue is more characteristic of MFC.<sup>97</sup>

### Treatment

The goal of treatment is to manage inflammation and its complications (CME and CNV). MFC can present with significant anterior and posterior inflammation. Corticosteroids (topical, periocular, intraocular, and systemic) are used. Corticosteroid-sparing immunomodulatory agents become necessary when corticosteroids are not tolerated or recurrence is frequent. TNF- $\alpha$  inhibitors, such as adalimumab, can also be used in conjunction

with these corticosteroid-sparing immunomodulatory agents in particularly recalcitrant cases. CNV is primarily managed with anti-VEGF injections. Other management strategies for CNV include thermal laser, if extrafoveal, and very rarely PDT. Generally, this is done in conjunction with management of inflammation. Immunosuppressive agents may be most effective in the early stages of CNV development.<sup>98</sup> Spontaneous involution of CNV can occur. No treatment may be necessary if the lesions are not sight threatening. Therapy of the diffuse photoreceptor damage occasionally seen is uncertain.

## MULTIPLE EVANESCENT WHITE DOT SYNDROME

### Epidemiology and Pathogenesis

MEWDS is an inflammatory chorioretinopathy that affects predominantly young, healthy women in their second to fourth decades of life. A flu-like illness often precedes the eye symptoms in about one half of the patients.<sup>99</sup>

### Ocular Manifestations

Patients with MEWDS have acute, unilateral, painless visual loss.<sup>99</sup> Rarer bilateral MEWDS that is asymmetrical has been reported.<sup>100</sup> Patients often complain of a scotoma and associated shimmering photopsias, often in the temporal visual field. Ocular findings include a variable number of small, white spots at the level of the deep retina. These are concentrated in the paramacular area and less prominent beyond the vascular arcades (Fig. 7.22.8). A characteristic granular appearance to the fovea is usually present acutely, and the fovea usually does not return to a normal appearance (see Fig. 7.22.8).<sup>99</sup> In atypical cases, this may be the only presenting feature.<sup>101</sup> Variable amounts of vitritis and optic disc edema are present. Retinal vascular sheathing may also be seen. Rarely, a progressive geographical circummacular discoloration or white lesion can be the presenting sign.<sup>102</sup> Mild pigmentary changes may develop with the resolution of the white spots. Choroidal scarring resembling MFC is possible in some patients. Rarely, CNV can develop and may be the presenting sign.<sup>103</sup> About 10% of cases may show recurrences.<sup>100</sup>

### Diagnosis

Diagnosis is made clinically. Visual field testing may reveal enlargement of the blind spot.<sup>99,104</sup> FA may reveal leakage from disc capillaries and late retinal punctate staining, characteristically in the shape of a wreath (Fig. 7.22.9).<sup>99,104</sup> Leakage in the macula in a noncystoid pattern may be seen. ICGA demonstrates multiple hypofluorescent (more than are clinically seen or detected on fluorescein) areas in the posterior pole.<sup>105</sup> Dots on spots are seen (see below), and OCTA shows no abnormalities in the superficial or deep choroidal or retinal circulation.<sup>106</sup> SD-OCT shows hyper-reflective multifocal debris at the ellipsoid layer, with dome-shaped protrusions of the hyperreflectant material from the ellipsoid layer toward the outer nuclear layer corresponding to the location of perifoveal dots seen with photography.<sup>107,108</sup> The larger confluent “spots” are hyporeflective and localized to the level of the ellipsoid zone, with disruption of the IS/OS junction.<sup>106</sup> All these changes resolve spontaneously. In addition, although lesions typically occur unilaterally, photoreceptors can rarely have abnormalities bilaterally.<sup>109</sup> FAF shows hypofluorescent spots and dots in greater numbers than clinically seen.<sup>110,111</sup> ERG may reveal a profoundly decreased a-wave amplitude and early receptor potential amplitudes in the acute phase of the disease, suggesting widespread photoreceptor dysfunction.<sup>112</sup> During the recovery, these amplitudes return to normal. In addition, prolonged regeneration kinetics of the RPE also are present in the acute phases of the disorder.<sup>112</sup> The exact mechanisms of visual loss in MEWDS are not understood well but probably represent photoreceptor dysfunction.

### Differential Diagnosis

Diagnosing MEWDS can be challenging because of the transient nature of clinical findings. MFC may have evanescent white spots. Lymphoma may produce white lesions. Sarcoidosis and diffuse unilateral subacute neuroretinitis should also be considered. In young healthy patients presenting with unilateral vision loss (often with an abnormal fovea), MEWDS must be considered because it may present after the white spots have subsided<sup>113,114</sup> (Box 7.22.7).

**Fig. 7.22.8 (A) Right Eye of a Woman With Multiple Evanescent White Dot Syndrome.** Note the multiple white spots throughout posterior pole and (B) the granular appearance of the fovea.

## Course and Outcomes

Because MEWDS has a self-limiting course, no specific treatment is indicated.<sup>99</sup> The white dots fade, and disc edema gradually resolves, usually within 2–6 weeks of the onset of symptoms and ocular findings. Visual acuity gradually returns to baseline levels. The temporal scotoma and photopsias may take considerably longer to improve (several months).<sup>99</sup> Recurrences have been reported.<sup>100</sup> Visual prognosis is good, even among patients who have recurrences. A very rare association with AZOOR has also been reported.<sup>115</sup> OCT can be helpful to monitor the course of the disease. The recovery of photoreceptors is a good prognosticator. CNV, although rare, can affect the prognosis negatively.

## ACUTE ZONAL OCCULT OUTER RETINOPATHY

### Epidemiology

Although AZOOR is often included in the WSS, no clinical white spots are observed in this condition. AZOOR is a disorder that predominantly affects young, healthy women in their second to fourth decades of life.<sup>116</sup> Patients develop photopsia and complain of a dense scotoma related to outer retinal dysfunction. The condition may be unilateral or bilateral.

**Fig. 7.22.9** Late hyperfluorescent leakage from disc capillaries and late punctate staining, characteristically in the shape of a wreath, with diffuse late leakage in a nonpetaloid fashion in (A) early- and (B) late-phase fluorescein angiography image of the left eye of a patient with multiple evanescent white dot syndrome.

### BOX 7.22.7 Differential Diagnoses in Multiple Evanescent White Dot Syndrome

- Multifocal choroiditis/punctate inner choroidopathy
- Lymphoma
- Sarcoidosis
- Diffuse unilateral subacute neuroretinitis
- Infectious retinitis

Systemic autoimmune diseases have been noted in some patients with AZOOR.<sup>2,117</sup>

## Ocular Manifestations and Diagnosis

On initial examination, the fundus appears normal. Narrow retinal vessels and depigmentation of the RPE are found within months of onset of symptoms. These correspond to zones of visual field loss. Often, there is a sharp demarcation between normal retina and abnormal retina that has a curvilinear appearance. The scotoma is often contiguous with the disc. The eyes are usually quiet, but some vitreous cell may be present. In a possible variant of classic AZOOR, called *acute annular outer retinopathy*,

**BOX 7.22.8 Differential Diagnoses in Acute Zonal Occult Outer Retinopathy**

Hereditary retinal diseases (retinitis pigmentosa)  
 Cancer-associated retinopathy/melanoma-associated retinopathy  
 Autoimmune retinopathies (without cancer)  
 Diffuse unilateral subacute neuroretinitis  
 Optic neuropathies (Leber's optic neuropathy)

a gray-white line is visible between normal and abnormal retina.<sup>118</sup> The abnormal retina becomes atrophied, as seen in classic AZOOR.

FA findings typically are normal during the early phases of the disorder. Once RPE changes occur, pigment mottling and window defects develop in the involved areas. ICGA demonstrates a trizonal pattern in late-stage AZOOR with a normal appearance outside the AZOOR line (zone 1), minimal late leakage in the subacute area (zone 2), and hypofluorescence with choriocapillaris atrophy (zone 3).<sup>119</sup> SD-OCT shows disruption of the ellipsoid zone and interdigitation line (cone outer segment tips) with thickened outer plexiform layer (OPL) and loss of the outer nuclear layer (ONL). With healing, RPE atrophy and persistent loss of the ONL and ellipsoid zone are seen. In subacute or chronic AZOOR lesions, a trizonal pattern is seen with a normal appearance outside the AZOOR line (zone 1), drusen-like multifocal subretinal deposits (zone 2), and photoreceptor, RPE, and choroidal atrophy (zone 3).<sup>119,120</sup> FAF imaging reveals hypoautofluorescence in areas of severe involvement and hyperautofluorescence at the margins of these areas.<sup>121</sup> Again, a trizonal pattern is present in older lesions with normal autofluorescence in zone 1, speckled hyperautofluorescence with in the AZOOR lesion (zone 2), and hypoautofluorescence with choroidal atrophy (zone 3).<sup>119</sup> The outer retinal dysfunction can be documented by using visual field testing, which shows large, superior, temporal, and, occasionally, central zones of visual field loss. The scotomas often increase in size within a few days to months and may stabilize or progress. Visual field loss often occurs in both eyes but can be asymmetrical. Some improvement has been reported. Focal ERG reveals abnormalities in the area of the scotoma. Full-field ERG shows moderate to severe reduction in a-wave amplitude.<sup>122</sup> EOG testing is usually abnormal. Laboratory evaluation, including testing for antiretinal antibodies, is not helpful.

**Differential Diagnosis**

The differential diagnoses for AZOOR are listed in [Box 7.22.8](#).

**Course and Outcome**

Patients may show progression or recurrences with new areas of involvement. No specific treatment for AZOOR has been established. Glucocorticoids, immunosuppression, and antiviral agents have been tried but have not been proven to be efficacious. Although most patients retain visual acuity of better than 20/40 (6/12), permanent and occasionally severe visual field loss can occur.

Gass used the term *AZOOR complex*<sup>88</sup> to include MEWDS, AIBSE, AMN, PIC, and MFC. He felt that similarities existed in the demographics of these entities as well as in their effects on the outer retina. Multimodal imaging can now usually distinguish one disease from the other.

**ACUTE MACULAR NEUORETINOPATHY****Epidemiology and Pathogenesis**

AMN occurs in the second to fourth decades of life.<sup>123</sup> The disease process may be unilateral or bilateral. Rarely, there may be recurrences in one or both eyes. A history of a viral prodrome, trauma, or drug use (sympathomimetics) has been noted.<sup>124</sup> Many vascular causes have now been described.<sup>125</sup> Patients complain of decreased vision, paracentral scotomas, or both. The exact cause of AMR remains unknown. Newer imaging modalities have shown that the middle retina and the outer retina are involved.<sup>126–131</sup> Fawzi et al. found that the disease starts at the level of the

**BOX 7.22.9 Differential Diagnoses in Acute Macular Neuroretinopathy**

Multiple evanescent white dot syndrome  
 Paracentral acute middle maculopathy  
 Old inner retinal infarcts  
 Post-blunt ocular injury retinal thinning

outer plexiform layer and then rapidly involves the outer retina.<sup>132</sup> Multimodal imaging has indicated that a deep retinal vascular insult may cause this entity. It is important to discuss the retinal vascular anatomy to better understand AMN. OCTA has confirmed that there are three capillary layers of the retina in the posterior pole (a fourth is found along the temporal arcades).<sup>133</sup> The innermost layer is the superficial plexus (SCP), followed by the intermediate (ICP) and then the outermost layer, called the *deep capillary plexus* (DCP). A vascular insult to the SCP creates a cotton wool spot, whereas an insult to the ICP will result in a deeper defect called paracentral acute middle maculopathy (PAMM). Finally, vascular compromise to the DCP causes AMN.

**Diagnosis**

Ophthalmoscopy reveals one to several small, circular, oval, or petaloid dark lesions that surround the fovea. These may appear darker red or brown than the surrounding normal macula. Diagnosis usually is made on the basis of the clinical course and appearance of the lesion. The lesions are best seen on red-free photographs, infrared reflectance (IR) images, or OCT images. FA and ICGA results are normal. OCTA, however, may demonstrate areas of flow deficits in the deep retinal vascular plexus corresponding to the macular lesion(s) in the enface and B-scan images. Initial SD-OCT shows a hyperreflective band involving the OPL and ONL, with associated disruption of the ellipsoid and interdigitation zones. Over several weeks, there is improvement in hyperreflectivity, but punctate hyperreflective areas persist within the OPL and ONL. Thinning of the ONL occurs.<sup>132</sup> The ellipsoid and interdigitation zones are partially restored ([Fig. 7.22.10](#)).<sup>134</sup> Infrared SLO and near-infrared FAF images highlight the lesions well.<sup>132,134</sup> These, along with OCT images, show rapid changes over the first few weeks of disease. Very subtle pigmentary changes involving the RPE have been suggested to cause the reddish AMN lesions.<sup>132</sup> Visual field testing often reveals paracentral scotomas that correspond to the shape and location of the macular lesions. Electrophysiological testing results, except those of multifocal ERG, are normal.

**Differential Diagnosis**

The differential diagnoses for AMN are listed in [Box 7.22.9](#).

AMN should be further distinguished from PAMM. Sarraf et al. coined the term PAMM in 2013.<sup>127</sup> These patients also present with acute scotomas, and gray or reddish lesions may be seen clinically. However, multimodal imaging shows an insult to the ICP rather than to the DCP. PAMM has been found in other vascular disorders, such as diabetes and vein occlusions.<sup>131</sup>

**Course and Outcomes**

No treatment is known for AMN, but the active lesions are usually self-limiting. Visual acuity may improve, and the paracentral scotomas may decrease in size; however, resolution of symptoms may take months. The acute retinal lesions fade but do not resolve completely, and loss of the ONL is seen. PAMM and AMN can be distinguished by using multimodal imaging, and these entities are being increasingly recognized.

**ACKNOWLEDGMENT**

The authors would like to acknowledge Tho Le Phuong Tran for her research assistance in the preparation of this manuscript.

**Fig. 7.22.10 Acute Macular Neuroretinopathy (AMN).** Infrared reflectance (IR) and optical coherence tomography (OCT) at baseline (*top*) shows wedge-shaped, dark lesions on IR. OCT shows outer nuclear layer (ONL) hyperreflectivity and disruption of the inner segment/outer segment (IS/OS), and OS/RPE lines. The 14-month follow-up (*bottom*) shows fading of the lesion on IR. OCT shows normal reflectivity of the ONL, with focal thinning in the areas that were previously involved. The IS/OS lines have completely normalized, but the OS/RPE lines remain absent in the regions of the original AMN lesion. OCT evidence of OS/RPE disruption and ONL thinning, as well as the fading IR lesion, may be long-term markers. (Courtesy Amani Fawzi, MD, Northwestern University.)

## Masquerade Syndromes: Neoplasms

7.23

Nirali Bhatt, Chi-Chao Chan, H. Nida Sen

**Definition:** Simulation of an inflammatory condition by a neoplastic process.

## Key Features

- Usually bilateral but may have asymmetrical involvement.
- Cells in aqueous or vitreous humor or both.
- With primary central nervous system (CNS) lymphoma: subretinal pigment epithelium lesions, CNS involvement, patients typically >50 years of age.

## Associated Features

- May respond initially to corticosteroids, but eventually becomes “corticosteroid resistant”.
- Older age or known history of malignancy elsewhere.
- Usually a lack of inflammatory features, such as keratic precipitates and synechiae, but not universally.

## INTRODUCTION

Masquerade syndromes are a rare group of disorders that mimic ocular inflammatory disease. They can be infectious or neoplastic, but they commonly refer to a neoplastic process. The term “masquerade syndrome” was first used in ophthalmology by Theodore in 1967 to describe a conjunctival carcinoma that presented as chronic conjunctivitis.<sup>1</sup> Neoplastic masquerade syndromes constitute a minority of cases (2.3%) in uveitis clinics.<sup>2</sup> Early recognition of masquerade syndromes is critical, as infectious masquerade syndromes are potentially curable, and recognition of neoplastic masquerade syndromes can be life-saving.

## PRIMARY NEOPLASMS

## Primary Intraocular (Vitreoretinal) Lymphoma

Primary intraocular lymphoma (PIOL), renamed as primary vitreoretinal lymphoma (PVRL), is a subset of primary central nervous system lymphoma (PCNSL). It is typically an extranodal non-Hodgkin's, diffuse large B-cell lymphoma (DLBCL), which presents in the eye with or without simultaneous central nervous system (CNS) involvement.<sup>3,4</sup> Various studies have reported that 56%–90% of patients with PVRL have or will develop CNS disease, whereas 15%–25% of patients with PCNSL present with or ultimately develop PVRL.<sup>3</sup> In contrast to systemic DLBCL and similar to PCNSL, extracerebral dissemination is very rare. PVRL is a challenging malignancy with high rates of morbidity and mortality. It affects patients in their sixth to seventh decades. The incidence is higher in men, and there is no racial predilection. PVRL is bilateral in approximately 80%–90% of patients but can be unilateral at presentation. The incidence of PVRL is approximately 380 persons/year in the United States.<sup>5,6</sup>

PVRL typically masquerades as chronic intermediate uveitis that is unresponsive or poorly responsive to corticosteroids. Patients present with blurred vision and floaters; vitreous cells (usually in sheets); vitreous haze; multifocal, elevated, cream-colored, subretinal infiltrates; and, less commonly, anterior chamber inflammation, keratic precipitates, exudative retinal detachment, or retinal pigment epithelium (RPE) detachments (Fig. 7.23.1). Clinically, PVRL can mimic autoimmune or infectious uveitides, such as sarcoidosis, tuberculosis, viral retinitis, Behçet's disease, Vogt-Koyanagi-Harada disease, and toxoplasmosis, often leading to delayed

diagnosis.<sup>7,8</sup> Human immunodeficiency virus (HIV)-associated PCNSL, which occurs in younger patients, should also be considered in the differential diagnosis. The incidence of PCNSL in HIV is 2%–6%, at least 1000 times more than the rate for the average population. It occurs with low CD4 counts (<50–100) and is closely related to Epstein-Barr virus (EBV).<sup>3,6</sup>

## Diagnosis

Definitive diagnosis of PVRL requires identification of malignant lymphoma cells in ocular specimens. Specimens for diagnosis include vitreous, aqueous, or chorioretinal biopsy. It is essential to collaborate with the ocular pathologist to optimize specimen handling.<sup>9</sup> CNS involvement can lead to neurological deficits, including hemiparesis, ataxia, neuropsychiatric symptoms, and behavioral changes.<sup>10</sup> Therefore, magnetic resonance imaging (MRI) and lumbar puncture with cerebrospinal fluid cytology is crucial, even if patients are asymptomatic (Fig. 7.23.2). Brain biopsy may be necessary in select cases.

Chorioretinal biopsy and diagnostic enucleation demonstrate that lymphoma cells are located between the RPE and Bruch's membrane, but these cells may invade the vitreous and the retina. A complete diagnostic vitrectomy in the eye with more “vitritis” and worse vision is recommended. Undiluted fresh vitreous (1–2 mL) should be placed into cell culture medium and immediately transported for processing. Cytology reveals atypical lymphoid cells with scanty basophilic cytoplasm and large, irregular nuclei with prominent (or multiple) nucleoli (Fig. 7.23.3). Reactive T lymphocytes, necrotic cells, fibrin, and debris are often present.<sup>3,9</sup>

Immunohistochemistry or flow cytometry is helpful in determining monoclonality. Most PVRL specimens stain positively for B-cell markers and show restricted expression of either  $\kappa$ - or  $\lambda$ -chain. T-cell markers help identify rare cases of T-cell lymphoma.<sup>3</sup> Demonstration of rearrangement of the immunoglobulin heavy chain (*IgH*) or *TCR* gene by using microdissection and polymerase chain reaction also indicates monoclonality. A high ratio of interleukin-10 (IL-10) (a cytokine secreted by B cells) to IL-6 (proinflammatory cytokine) is suggestive of PVRL and a ratio >1 has a reasonably high sensitivity and specificity but is not diagnostic.<sup>3,9</sup>

False-negative results can occur as a result of improper handling and processing of specimens, corticosteroid use, or simply because of paucity of neoplastic cells in the specimen. A quick taper of corticosteroids preoperatively should be considered. Repeated diagnostic vitrectomies may be required in some cases when more neoplastic cells break through the retina.

Multimodal imaging with fundus photography, fundus autofluorescence (FAF), fluorescein angiography (FA), and optical coherence tomography (OCT) may aid in diagnosis and follow-up.<sup>11,12</sup> The most frequent FA finding in PVRL is a “leopard spot” pattern of granular hypofluorescence, reported in 43%–61% of eyes in a published series, which characteristically correlates with the yellow infiltrates apparent on examination. FAF is also associated with a granular appearance in PVRL. Areas seen as hypofluorescent on FA correspond to hyperautofluorescent spots on FAF. Following treatment of PVRL, patchy hypofluorescence caused by RPE atrophy can occur in areas of prior activity. Abnormalities visualized at the subretinal or RPE level are the most commonly reported OCT findings of PVRL and have ranged in frequency from 41.7% to 75% of eyes. These can include subretinal hyperreflective nodules, RPE irregularities, subretinal fluid, and separation of the RPE from Bruch's membrane. Less commonly, intraretinal hyperreflective infiltrations and disruption of the ellipsoid zone have also been reported.

## Treatment

The diagnosis and treatment of PCNSL/PVRL require a multidisciplinary approach and is best achieved in large centers that have experience. Median survival without specific therapy is 1.9–3.3 months.<sup>13</sup> PCNSL is

**Fig. 7.23.1** Diffuse stellate-like keratic precipitates (A) and vitreous cells in “sheets” in a patient with primary vitreoretinal lymphoma (PVRL) (B). Multiple, elevated, creamy subretinal lesions along the superior arcade and the optic nerve on fundus photography (C) correspond to the early blockage outlined by arrows on fluorescein angiography (D). There is also punctate hyper- and hypofluorescence surrounding the lesions reminiscent of a “leopard spot” pattern outlined by arrows both on fluorescein angiography (FA) and autofluorescence (E).

**Fig. 7.23.2** Central nervous system (CNS) involvement in a patient with primary vitreoretinal lymphoma/primary central nervous system lymphoma (PVRL/PCNSL) with multiple enhancing lesions with the largest  $\approx 2.5$ -cm homogenous spherical lesion (arrows) centered in the left hypothalamus.

sensitive to chemotherapy and radiotherapy (RT), but the outcomes are still poor compared with other lymphomas. Most therapies used for systemic lymphoma have been ineffective for PCNSL. With the exception of stereotactic biopsy, surgical tumor resection is not done in the treatment of PCNSL. RT had been the standard of care until 1990s. Since then, high-dose methotrexate (MTX) with or without RT has been the mainstay

of therapy with an overall survival of 24–40 months. In addition to MTX, cytarabine, Ara-C, glucocorticoids, and temozolomide are also used. Rituximab, an anti-CD20 monoclonal antibody, is now used in combination with chemotherapy, although its role in PCNSL is still uncertain despite its effectiveness in other lymphomas.<sup>14</sup> The roles of intrathecal chemotherapy and stem cell transplantation remain unclear. Intravitreal methotrexate (400  $\mu\text{g}$  in 0.1 mL) or rituximab (1 mg in 0.1 mL), alone or in combination, or ocular RT can be administered for isolated ocular recurrences or to supplement systemic therapy in PVRL.<sup>3</sup> Overall survival in patients with PVRL is 58 months, with the majority of recurrences occurring in the CNS. Local ocular therapy will not prevent CNS recurrences, and patients should be monitored closely with regular MRIs, neurological and ocular examinations. The long-term prognosis for patients with PCNSL remains poor. Multiple factors, including age, performance status, neurological function, and the number and location of lesions, can influence survival in patients with PCNSL.<sup>7,14</sup>

### Primary Choroidal Lymphomas and Lymphoid Hyperplasia

First described in 1920, primary choroidal lymphomas are typically extranodal marginal zone, mucosa-associated lymphoid tissue (MALT) lymphomas.<sup>3</sup> They are rare and are not associated with CNS disease. Because they are typically low-grade B-cell lymphomas with an indolent clinical course, they were previously termed “uveal or intraocular pseudo-tumor” and “reactive lymphoid hyperplasia.” Recent studies have confirmed that lymphoid hyperplasia is, indeed, a lymphoma.<sup>15</sup> Early diagnosis is usually based on multifocal creamy choroidal infiltrates, choroidal thickening on ultrasonography, and extraocular extension leading to orbital mass or salmon-colored conjunctival mass. It carries a favorable prognosis, with very low rates of systemic metastasis, and frequently responds to corticosteroids or low-dose RT.<sup>15</sup>

Posttransplantation lymphoproliferative disorders (PTLDs), potentially fatal complications of chronic immunosuppression, are extranodal non-Hodgkin’s lymphoma (NHL) of large-B-cell type. Its pathogenesis is closely related to EBV and the degree of immunosuppression.

### Melanoma

Ocular melanoma is the most frequent neoplasm of the eye, with a 5.1 per 1000000 annual incidence in the United States, arising from the uveal

**Fig. 7.23.3** Gross photograph of an enucleated eye with primary vitreoretinal lymphoma (PVRL) with retinal thickening and subretinal tumor infiltration (A). Photomicrograph showing immunohistochemical staining of lymphoma cells from the vitreous with positive staining for CD-20, a B-cell marker (B), and large lymphoma cells with scanty basophilic cytoplasm and large hypersegmented nuclei and prominent nucleoli (Giemsa stain) (C).

tract in 97% of cases.<sup>16</sup> It mainly affects white patients in their early 60s, and approximately 5% of uveal melanomas present with ocular inflammation with iridocyclitis or with dilated episcleral vessels (“sentinel vessels”) that can be misdiagnosed as scleritis. Focal choroidal mass can mimic a choroidal granuloma, sectoral cataract, posterior scleritis, secondary glaucoma, or retinal detachment. Ultrasonography shows characteristic low internal reflectivity. The most common sites for metastases are the liver, lungs, and skin. All patients require metastatic evaluation prior to therapy. Treatment includes radiation (brachytherapy, external beam radiotherapy, and transpupillary thermotherapy), or surgery (transscleral partial choroidectomy, transretinal endoresection, and enucleation). Adjuvant therapy may consist of RT or systemic therapy, such as chemotherapy, immune therapy, hormone therapy, biological therapy, or target therapy. Prognosis is fair, with a 5-year survival of approximately 50%–80%, but this largely depends on the nature of melanoma.<sup>16,17</sup>

### Other Primary Neoplasms

A small percentage of retinoblastomas (RBs) (1%–3%) can present as ocular inflammation with a shifting pseudo-hypopyon and vitritis. Patients are typically young children with diffuse infiltrating retinoblastoma. Computed tomography (CT) may not be helpful because of lack of calcification. Aqueous aspiration should be avoided if RB is suspected because of the risk of tumor spread.<sup>18</sup>

Juvenile xanthogranuloma (JXG), a benign cutaneous fibrohistiocytosis of infancy, is characterized by reddish-yellow nodules of the skin, eye and rarely viscera. Yellowish iris nodules can masquerade as inflammatory granuloma. Anterior chamber cells, heterochromia, iris thickening, and spontaneous hyphema can masquerade as pediatric anterior uveitis. Histopathology illustrates large foamy histiocytes and Touton giant cells. Prognosis is often favorable, with good response to topical, local, or systemic corticosteroids.<sup>19</sup>

**Fig. 7.23.4** Fundus photograph of a patient with choroidal mucosa-associated lymphoid tissue (MALT) lymphoma shows deep multifocal faintly creamy choroidal infiltrates in the posterior pole (A) showing mild staining in corresponding areas on fluorescein angiography (FA) (B). The gross photograph of another typical choroidal MALT lymphoma shows diffuse choroidal infiltration (C). The photomicrograph of the choroidal lymphoma in the patient (A–B) shows Dutcher bodies (arrows) admixed with numerous atypical lymphocytes in the choroid (D).

## SECONDARY NEOPLASMS AND METASTASES

### Lymphoma and Leukemia

Secondary lymphomas represent metastatic systemic lymphoma and are usually confined to the choroid. Metastatic lymphomas are less of a diagnostic challenge because most patients have a known history at presentation. They often exhibit creamy choroidal/subretinal infiltrates (Fig. 7.23.4). Diffuse choroiditis, retinal vasculitis, or necrotizing retinitis may be present. Ocular adnexa and anterior segment can also be affected causing hypopyon and anterior uveitis. The most common metastatic lymphoma involving the choroid is DLBCL. Average survival in these patients is <3 years after ocular diagnosis. Most orbital/adnexal lymphomas are MALT lymphomas with good prognosis (10-year survival ≈80%).<sup>3,20</sup>

Less frequently, multiple myeloma, extramedullary plasmacytoma, lymphoplasmacytic lymphoma/immunocytoma (including Waldenström's macroglobulinemia), B-cell chronic lymphocytic leukemia, and, very rarely, intravascular lymphoma can also lead to similar findings.<sup>3,21</sup> Peripheral T-cell lymphomas, a rare group of disorders with generally poor prognosis,

and mycosis fungoides (cutaneous T-cell lymphoma) are rarely responsible for ocular involvement and not only typically present with anterior segment or external involvement but can also cause vitritis, exudative RD, papilledema, and even PVRL. Adult T-cell leukemia/lymphoma is caused by human T-lymphotropic virus-1, a retrovirus endemic in Japan, Caribbean islands, and central Africa. It can present with retinal vasculitis, subretinal infiltrates, macular edema, vitritis, anterior uveitis, keratopathy, or episcleritis.<sup>22</sup> Patients with leukemia can present with retinal hemorrhages, cotton wool spots, Roth spots, retinal microaneurysms, or neovascularization. It can also cause vitritis, exudative RD, pseudo-hypopyon, hyphema, and iris heterochromia. Differentiation between PVRL and metastatic lymphoma/leukemia is critical from a therapeutic standpoint because the former requires chemotherapy that crosses the blood–brain barrier.

### Metastatic Carcinoma

Uveal metastases, particularly to the choroid, are the most common intraocular malignancies in adults. Most common primaries are lung and breast cancers. In the case of breast carcinoma, >90% patients have a

known primary history, whereas this is not the case with regard to lung carcinoma. Common findings are bilateral choroidal involvement; multifocal gray-yellow, relatively flat lesions that can be associated with vitritis; exudative RD or a “leopard spot” pattern; and papilledema. Most patients also have CNS metastasis and have a poor prognosis, with an average survival of <1 year.<sup>23</sup>

## Metastatic Melanoma

Metastatic melanoma to the eye is extremely rare and can involve the uvea or the orbit. It can manifest as exudative RD or RPE detachments, clumps of pigmented or nonpigmented vitreous cells, hyphema, neovascular glaucoma, or vitelliform retinopathy. Prognosis is very poor.<sup>24</sup>

## Paraneoplastic Syndromes

Paraneoplastic autoimmune retinopathy can masquerade as uveitis. Patients can present with photopsiae, nyctalopia, photoaversion or dyschromatopsia, vision loss, mild vitritis, and, less frequently, macular edema, but the fundus can look normal in the early stage. Later, vascular attenuation, optic nerve pallor, and RPE disturbances may ensue. Electroretinography (ERG) and visual field testing show scotomas and decreased cone and rod responses. Cancer-associated retinopathy (CAR) is most commonly associated with oat cell carcinoma of the lung. Anti-recoverin antibody is the characteristic autoantibody, but is not unique to CAR. Melanoma-associated retinopathy (MAR) is a complication of metastatic cutaneous melanoma. ERG findings are characteristic with negative b-wave and relatively preserved photopic responses. Responsible autoantibody targets TRPM1 channel on ON-bipolar cells. Typically, retinopathy precedes cancer in CAR, whereas it follows the diagnosis of melanoma by months to years in MAR. Therapy is aimed at treating the underlying malignancy. Local or systemic corticosteroids, intravenous immunoglobulin and plasmapheresis have been tried.<sup>25,26</sup>

Bilateral diffuse uveal melanocytic proliferation, a very rare paraneoplastic syndrome that occurs in patients with occult carcinoma, is characterized by multiple subtle subretinal reddish-brown lesions, which show

hyperfluorescence on angiography, exudative RD, thickening of the uvea, mild uveitis, and rapidly progressive cataracts. Histopathology shows melanocytic hyperplasia.<sup>27</sup>

## CONCLUSIONS

The most important step in the diagnosis of neoplastic masquerade syndromes is clinical suspicion. A thorough history, systemic review, and careful ophthalmic examination aided by appropriate ancillary testing are required. Early recognition of the malignancy is crucial for both vision-saving and life-saving outcomes, which can be achieved through a multidisciplinary approach.

# Malignant Intraocular Neoplasms

James J. Augsburger, Zélia M. Corrêa, Jesse L. Berry

## 8.1

**Definition:** Spectrum of intraocular tumors composed of malignant neoplastic cells capable of destroying normal intraocular tissues by expansion and invasion, extending outside the eye, and/or spawning extraophthalmic metastatic tumors.

### Key Features

- Shape:
  - Most appear as discrete nodular tumors (e.g., primary uveal melanoma, medulloepithelioma, intraocular metastases, some retinoblastomas, occasional primary intraocular lymphoma).
  - May vary substantially among the different malignant tumor types (e.g., many posterior uveal melanomas [about 20%] exhibit a mushroom-like three-dimensional shape; most subretinal pigment epithelium infiltrates in primary vitreoretinal lymphoma exhibit a geographic basal configuration; most metastatic choroidal tumors exhibit a broad base but limited thickness and are more likely to be multinodular than most other tumor types).
  - Some appear as ill-defined infiltrates in the vitreous (e.g., primary vitreoretinal lymphoma, intraocular leukemia, retinoblastoma with vitreous seeding), some of which have no associated discrete intraocular tumor(s).
  - Some (e.g., diffuse posterior uveal melanoma, diffuse posterior uveal lymphoma, some cases of diffuse intraocular retinoblastoma) appear as broad-based (i.e., largest basal diameter >15 mm) but relatively thin tumors (i.e., having a maximal thickness <20% of the tumor's largest basal diameter).
  - Uveal melanomas in the ciliary body can assume a ring shape.
- Color:
  - Most primary uveal melanomas are brown to gray (although nearly 15% are clinically amelanotic).
  - Most retinoblastomas are white (although some of a pink to orange color depending on the density of superficial retinal capillaries in the tumor).
  - Most metastatic carcinomas to the choroid are pale yellow to nearly white (although some, such as thyroid carcinoma, renal cell carcinoma, carcinoid tumors, and choriocarcinoma tend to be red to pink to orange and most metastatic skin melanomas are golden brown to dark brown).
  - Most medulloepitheliomas are off-white.
  - Most subretinal pigment epithelium infiltrates of primary vitreoretinal lymphoma are pale yellow to golden.
- Laterality/Focality:
  - Primary uveal melanomas and medulloepithelioma are almost exclusively unilateral and unifocal.
  - Retinoblastoma, uveal metastases, and primary vitreoretinal lymphoma may be unilateral and unifocal but may also occur bilaterally and/or multifocally.
- Growth:
  - Most untreated malignant intraocular tumors enlarge progressively.
  - Stable size may occur in dormant posterior uveal melanoma, retinomas, and metastatic uveal carcinomas in patients being treated by an effective systemic chemo- or immunotherapy.
  - Some malignant intraocular tumors (primary uveal melanomas, retinoblastoma, medulloepitheliomas) can extend outside the eye by invasive spreading.

### INTRODUCTION

A malignant intraocular neoplasm is a tumor (three-dimensional mass) that is present inside an eye and is composed of abnormal cells exhibiting features such as nuclear atypia and pleomorphism, prominent nucleoli, and abnormal nucleus-to-cytoplasm ratio sufficient to warrant their classification as malignant (cancer) cells by pathologists. These cancer cells can arise from previously normal cells that were present in their tissue of origin (*primary malignant intraocular neoplasms*), develop by intraocular invasion of cancer cells that arise from extraocular tissues adjacent the eye (e.g., conjunctiva, orbit) (*secondary malignant intraocular neoplasms*), or occur by hematogenous metastasis from a nonophthalmic primary malignant neoplasm remote from the eye (*metastatic malignant intraocular neoplasms*). Readers should note that many authors (and the ICDM coding system) lump secondary tumors and metastatic malignant intraocular neoplasms, as we define them, together under the term “secondary” and fail to address the distinction between these subtypes.

Some malignant neoplasms and neoplasias (nontumorous accumulations of malignant cells within a tissue) that metastasize to the eye, most notably the hematological neoplasias (leukemia and its variants), and some primary malignant ocular neoplasms (most notably primary vitreoretinal lymphoma and diffuse infiltrating retinoblastoma) frequently produce ill-defined infiltrates of intraocular tissues (e.g., vitreous, retina, optic disc) rather than discrete solid neoplastic tumors.

### PRIMARY MALIGNANT INTRAOCULAR NEOPLASMS

#### RETINOBLASTOMA

Retinoblastoma is a primary malignant intraocular neoplasm that arises from immature retinal cells (retinoblasts) within the developing retina. As retinoblasts mature and differentiate into adult cells, they lose their potential to give rise to retinoblastoma. Because of this, the vast majority of cases of active retinoblastoma are identified in children under the age of 6 years. Retinoblastoma is the most common primary malignant intraocular neoplasm in children worldwide.<sup>1</sup>

Almost all retinoblastoma tumors that have been studied cytogenetically exhibit inactivating mutations or deletions of both copies of the *RB1* tumor suppressor gene, which is located on the short arm of chromosome 13 (region q14) within all tumor cells.<sup>2</sup> These cytogenetic alterations can develop by chance in both copies of chromosome 13 within previously normal retinoblasts. Such occurrence is extremely uncommon in spite of the large number of retinoblasts that are present in the developing eye. Such genetic alterations usually give rise to unilateral unifocal retinoblastoma.

In contrast, these cytogenetic alterations can develop within retinoblasts that have a congenital mutation or deletion of the relevant segment of one of the two chromosomes 13 in some or all cells of the developing retina. All cells will be affected when the *RB1* tumor suppressor gene is defective and inherited from an affected parent (familial retinoblastoma) or when a mutation occurred early in embryogenesis prior to cellular differentiation into the neural epithelial precursors of the retina.<sup>2</sup> These cells can give rise to retinoblastoma if the normal *RB1* tumor suppressor gene also undergoes a chance mutation of chromosome 13q14 or a deletion of that portion or all of chromosome 13. Some cells will have a congenital chromosomal mutation or deletion of chromosome 13q due to an event in a precursor cell to some but not all of the retinoblasts in one or both eyes. In such

**Fig. 8.1.1** Asymmetric White Pupil (Leukocoria) of Both Eyes Due to Intraocular Retinoblastoma.

**Fig. 8.1.3** Massive Conjunctival Chemosis as Presenting Feature of Advanced Intraocular Retinoblastoma Associated With Massive Tumor Necrosis.

**Fig. 8.1.2** Small-Angle Left Exotropia as Presenting Feature of Retinoblastoma of Left Eye.

**Fig. 8.1.4** Massive Proptosis of Right Eye Due to Orbital Extension of Retinoblastoma.

cases, the mutation or deletion of chromosome 13q will not be present in the precursor cells that give risk to spermatocytes or oocytes; consequently, such cases will not be heritable even though the affected child may have multifocal retinoblastoma in one or both eyes. These variations in heritability lead to two forms of retinoblastoma: the *heritable* form, seen in 40% of patients, with a mutation in all cells of the body and a presentation, most often, with bilateral tumors, multifocal tumors, or both; and the *somatic* form, wherein both mutations are present only in the tumor tissue and the child usually manifests unilateral unifocal disease. However, 10%–15% of patients who present with unilateral retinoblastoma may still harbor the germline mutation. In view of this, blood testing for a germline mutation (or mosaicism) is advised for all children with retinoblastoma.<sup>2</sup>

The cumulative lifetime incidence of retinoblastoma in most ethnic and racial groups has been estimated to be approximately one case in 15 000–20 000 individuals.<sup>3</sup> As mentioned above, almost all active cases of retinoblastoma occur in children under the age of 6 years. Survivors of bilateral or known familial retinoblastoma who subsequently have children run nearly a 50% chance that any child they have will develop retinoblastoma.<sup>2</sup> Because many more children with bilateral and familial retinoblastoma are cured now than was possible in prior generations, the frequency of hereditary retinoblastoma may be increasing in the general population.

The clinical features of retinoblastoma differ substantially depending on the extent of ocular involvement at the time of initial detection. The most common presenting feature of retinoblastoma reported by parents of an affected child is that of a white appearance or glow of the pupil in one or both eyes (leukocoria) (Fig. 8.1.1). The second most common presenting feature is ocular misalignment (strabismus) (Fig. 8.1.2). Congestive ocular signs (Fig. 8.1.3) are quite uncommon except in very advanced cases. However, some children (principally ones in underdeveloped countries with poor access to healthcare professionals) do not have their

retinoblastoma identified until the eye is grossly hyperemic with profound chemosis or even proptosis (due to posterior extraocular extension of tumor to the orbit) (Fig. 8.1.4).<sup>4,5</sup>

Children suspected of having or developing retinoblastoma because of a positive family history of the disease should be screened for retinoblastoma shortly after birth and (if this baseline examination does not reveal any retinoblastoma) periodically thereafter during at least the first 2 years of life. In these children, retinoblastoma tumors that are detected are usually relatively small and predominantly intraretinal. In contrast, children who develop nonfamilial retinoblastoma are frequently not diagnosed until their intraocular tumors are much larger and the eye demonstrates leukocoria, strabismus, or both. Very small intraretinal tumors (i.e., ones that are  $\leq 1$  mm in diameter) appear as smudgy translucent to off-white intraretinal lesions (Fig. 8.1.5). Slightly larger tumors appear more opaque white but exhibit prominently dilated and tortuous retinal blood vessels and a fine network of superficial capillaries that frequently give the tumor a slightly pink appearance (Fig. 8.1.6). Still larger intraretinal tumors are likely to show a surrounding cuff of serous subretinal fluid and limited tumor seeding extending into the overlying vitreous or subretinal fluid (Fig. 8.1.7). Massive intraocular tumors (generally defined as larger than 15 mm in diameter) frequently grow outwardly toward the choroid and become associated with a bullous nonrhegmatogenous retinal detachment (*exophytic* growth pattern), inwardly toward the vitreous to appear as a fuzzy white mass associated with prominent vitreous seeding (*endophytic* growth pattern), or both (mixed growth pattern). In some advanced cases, tumor seeding by retinoblastoma is so extensive that the clouding of the vitreous obscures many of the features of the underlying tumor (Fig. 8.1.8) or associated subretinal fluid is so turbid that the underlying retinal tumor is difficult to visualize. In some cases, the retina is infiltrated diffusely by a fluffy white accumulation of tumor cells without formation of any discrete

**Fig. 8.1.5** Small Intraretinal Retinoblastoma Appears as a Poorly Defined Translucent Retinal Lesion.

**Fig. 8.1.6** Two Discrete Intraretinal Retinoblastoma Tumors Supplied by Retinal Vasculature.

retinal tumor or tumors (diffuse infiltrating growth pattern)<sup>6</sup> (Fig. 8.1.9). In rare cases, retinoblastoma tumor seeds extend from the vitreous into the aqueous and enter the anterior chamber (Fig. 8.1.10). Advanced intraocular cases also frequently develop iris neovascularization, which can cause abrupt change in color of the iris noted by the child's parents, secondary glaucoma, and buphthalmos.

Occasionally, a retinoblastoma tumor undergoes spontaneous growth arrest to form a lesion known clinically as *retinoma*.<sup>7</sup> The typical retinoma is partly calcific with an associated pale gray to dull pink soft tissue component (Fig. 8.1.11). The lesion does not have prominent feeder and drainer retinal blood vessels that are characteristic of active retinoblastoma tumors. A limited area of chorioretinal atrophy is sometimes evident underlying or surrounding such lesions. Some lesions of this type transform to active retinoblastoma later in life, and such transformations are likely to explain many if not most reported adult cases of retinoblastoma.

Rarely, an advanced case of intraocular retinoblastoma undergoes spontaneous necrosis followed by shrinkage of the affected eye (*phthisis bulbi*).<sup>7</sup> While some of these cases result in total destruction of all viable retinoblastoma, others have persistent active tumor that involves the retrobulbar optic nerve or orbit and leads ultimately to a progressive orbital tumor, intracranial extension, and metastasis.

Ocular B-scan ultrasonography allows confirmation of most discrete retinoblastoma tumors and usually reveals hyperreflective intralesional dots

**Fig. 8.1.7** Relatively Large Intraretinal Retinoblastoma Tumor Associated With Prominent Feeder and Drainer Retinal Blood Vessels. Smaller intralesional blood vessels can also be appreciated.

**Fig. 8.1.8** Prominent Vitreous Seeds of Retinoblastoma Partly Obscuring Underlying Retinal Tumor.

(foci of intratumoral calcification) that are nearly pathognomonic of retinoblastoma (Fig. 8.1.12). However, eyes with diffuse infiltrating retinoblastoma frequently show no discrete tumor nodules or foci of intralesional calcification.<sup>6</sup> In cases with advanced vitreous seeding or bullous retinal detachment, B-scan can identify the underlying retinal tumor(s) and allow approximate measurement of the individual tumors. In eyes with massive involvement by retinoblastoma, ocular ultrasonography is of limited value for evaluating the retrobulbar optic nerve and orbital soft tissue for involvement by tumor (because the intralesional calcification usually reduces the quality of the orbital images).

Computed tomography (CT) scanning of the orbits and brain can be performed to identify discrete retinal tumors containing foci of calcification, evaluate the optic nerve and orbit, and evaluate the brain in children with suspected retinoblastoma (Fig. 8.1.13). This method of evaluation is not generally advocated in centers where magnetic resonance imaging (MRI) is available for children with suspected bilateral or familial retinoblastoma (who are known to be susceptible to radiation-induced second

**Fig. 8.1.9** Diffuse Retinal Infiltration by Retinoblastoma (Diffuse Infiltrating Growth Pattern). No discrete mass or foci of intralesional calcification was appreciated on B-scan ultrasonography (not shown).

malignant neoplasms in the field of radiation therapy) because of the relatively high level of radiation exposure associated with this testing.

MRI of the orbits and brain (Fig. 8.1.14) also identifies discrete intraocular retinoblastoma tumors, detects massive optic nerve invasion by tumor and transscleral orbital tumor extension, and permits identification of any associated brain lesions without subjecting the patient to relatively high doses of ionizing radiation.<sup>8</sup>

Some children who have bilateral or familial retinoblastoma develop a retinoblastoma-like neoplasm in the pineal region of the brain (pineoblastoma).<sup>9</sup> The association of bilateral retinoblastoma and pineoblastoma (sometimes referred to as ectopic intracranial retinoblastoma) is known as *trilateral retinoblastoma*. MRI is effective for identifying this type of brain tumor when it is present.<sup>10</sup>

Children with clinically diagnosed or suspected retinoblastoma are usually evaluated by baseline ophthalmic examination under anesthesia to ascertain the number, size, and location of discrete retinal tumors in each eye and the presence and extent of features such as serous retinal detachment, vitreous seeding, and subretinal seeding. Fundus mapping and (if available) intraoperative fundus photography are performed to document the clinical findings in each eye, justify classification of the extent of intraocular retinoblastoma, and serve as a baseline for comparison with

**Fig. 8.1.13** Computed Tomography Scan of Unilateral Retinoblastoma of Right Eye Showing Sizeable Intraocular Tumor That Is Almost as White as Bone Due to Intralesional Calcification.

subsequent findings if a treatment intended to be eye preserving is provided. The extent of intraocular retinoblastoma is classified today in most retinoblastoma centers using the International Classification of Intraocular Retinoblastoma (ICIR).<sup>11</sup>

Initial treatment options for retinoblastomas range from primary enucleation of one or both eyes to no treatment at all (in the case of retinoma).<sup>12</sup> Factors influencing the treatment recommendation for intraocular retinoblastoma include age of the affected patient, clinically assessed activity versus inactivity (retinoma) of the tumors, extent of abnormalities attributable to active intraocular retinoblastoma (ICIR group) in each affected eye, the unilaterality versus bilaterality of involvement, and absence versus presence of trilateral retinoblastoma. Enucleation is generally recommended for advanced (ICIR group D or E) unilateral nonfamilial retinoblastoma,<sup>13</sup> whereas intravenous multidrug chemotherapy with a carboplatin-based regimen is commonly recommended for bilateral advanced intraocular retinoblastoma or bilateral retinoblastoma with macular involvement in each eye.<sup>14</sup> With increasing frequency in recent years, unilateral cases of retinoblastoma and occasional bilateral cases are treated by selective ophthalmic artery infusion chemotherapy,<sup>15</sup> most commonly using melphalan. Occasional patients with ICIR group A or B retinoblastoma are managed by focal treatments alone (transscleral cryotherapy,<sup>16</sup> focal laser therapy,<sup>17,18</sup> episcleral plaque radiotherapy<sup>19</sup>) without any concurrent chemotherapy. Many cases are treated by more than one method (combined modalities therapy; e.g., selective ophthalmic artery infusion chemotherapy plus local consolidation using cryotherapy, laser therapy, or both). Since 2012, vitreous seeding has been treated in some centers by intravitreal injection of one or more chemotherapeutic drugs,<sup>20</sup> most commonly melphalan, topotecan, or both. Intravitreal injection of chemotherapeutic drugs is not recommended as the initial or only treatment for any category of retinoblastoma, and extreme care must be taken to avoid any exteriorization of active intraocular retinoblastoma associated with this treatment.<sup>21</sup> External beam radiation therapy to both eyes of bilaterally affected children or the better eye of bilaterally affected children following enucleation of the worse eye, once the standard of care for such cases, is no longer advocated as initial therapy in most retinoblastoma centers because of the recognized potential for ionizing radiation to stimulate subsequent development of nonretinoblastoma “second malignant neoplasms” in the head and neck tissues that were in the field of radiation.<sup>22</sup> However, it is still used occasionally in attempt to salvage eyes that continue to harbor active retinoblastoma in spite of prior intensive systemic and local therapies.<sup>12,22</sup>

Children who are found to have pineoblastoma in association with their retinoblastoma (trilateral retinoblastoma) are treated with an aggressive regimen of intravenous chemotherapy, excision or focal radiation therapy to the residual central nervous system (CNS) tumor, and frequently by subsequent bone marrow transplantation.<sup>23</sup>

Children who have optic nerve invasion by retinoblastoma or orbital involvement by tumor are also treated by intravenous chemotherapy plus enucleation with debulking of the residual orbital tumor or external beam radiation therapy to the affected orbit.<sup>24</sup>

Children who have intracranial extension of retinoblastoma or metastasis of retinoblastoma are also managed by intensive intravenous chemotherapy, intrathecal chemotherapy, and subsequent bone marrow

transplantation (if the active retinoblastoma can be eradicated).<sup>25</sup> Unfortunately, a substantial proportion of children who develop intracranial extension or metastasis of retinoblastoma or intracranial pineoblastoma ultimately die of that cancer in spite of these aggressive interventions intended to eradicate it. In contrast, the vast majority (approximately 90%–95%) of children with clinically intraocular retinoblastoma at the time of diagnosis and initial treatment are cured of their cancer if appropriate treatment is provided.<sup>4</sup>

## PRIMARY UVEAL MELANOMA

Primary uveal melanoma is a malignant neoplasm that arises from previously normal melanocytes or nevus cells (slightly atypical but nonmalignant uveal melanocytes) within the uveal tract. While it has the potential to extend transclerally to the orbit, its principal danger is its potential to metastasize hematogenously to other organs, most notably the liver.<sup>26</sup> Most deaths attributable to primary uveal melanoma occur as a result of liver failure induced by metastatic tumors to that organ.<sup>27</sup>

The principal recognized risk factors for occurrence of primary posterior uveal melanoma are older patient age, white race, and presence of congenital ocular melanocytosis.<sup>26,28</sup> Primary uveal melanoma affects approximately one in 2000–2500 persons during their lifetimes. The annual incidence of primary uveal melanoma is less than one new case per million persons per year under the age of 20 years, approximately 7–8 new cases per million persons per year during the age range 55–65 years, and approximately 30–50 new cases per million persons per year during the age range 75–85 years. Light-skinned persons, particularly those of northern European extraction, have the highest risk for development of primary uveal melanoma, whereas dark-skinned persons have a very low risk for development of such tumors. Individuals with congenital ocular melanocytosis have a substantially increased likelihood of developing primary uveal melanoma in the involved eye.

Unlike retinoblastoma, primary uveal melanoma is almost exclusively a unilateral unifocal neoplasm. Also unlike retinoblastoma, primary uveal melanoma infrequently affects more than one individual in a family. However, individuals who are members of families that have an inheritable mutation in the BAP1 gene have been shown to be at increased risk for familial uveal melanoma as well as familial skin melanoma, renal cell carcinoma, and other malignant neoplasms.<sup>29</sup>

In most primary uveal melanoma cells that have been studied cytogenetically, mutations or deletions of several different chromosomes (principally chromosome 3, 8, 6, and 1) and of genes *GNAQ* and *GNA11* have been identified.<sup>30,31</sup> The mutations in *GNAQ* and *GNA11* appear to be necessary preliminary steps in the process that leads to development of uveal melanoma, but these gene mutations do not appear to have any prognostic significance with regard to emergence of metastasis.<sup>32</sup> In contrast, partial or complete deletion of one chromosome 3 (monosomy 3) has been shown to be of major prognostic significance. Patients having a primary uveal melanoma composed of tumor cells with monosomy 3 have a much higher probability of developing distant metastasis than those having disomy 3 of the tumor cells.

Although these prognostic markers do not aid in diagnostic or therapeutic management, many clinicians use this information to guide screening protocols aimed at the liver for the detection of metastatic disease, as discussed further in this chapter.

Primary uveal melanomas are divided conventionally into anterior and posterior subgroups. Anterior uveal melanomas are tumors that involve the iris, ciliary body, or both. Posterior uveal melanomas are those that involve the choroid alone or the choroid and ciliary body together. Occasional primary uveal melanomas involve all three portions of the uvea (i.e., choroid, ciliary body, and iris) simultaneously. Tumors of this type are usually grouped with the posterior uveal melanomas. This subdivision is a practical one that reflects relevant differences in clinical presentation, management, and outcomes.

## Primary Anterior Uveal Melanoma

Primary anterior uveal melanomas that involve the iris are frequently noted by the patient or family member as a newly apparent spot on the iris of one eye.<sup>33</sup> Because they are visible to the patient, such tumors tend to be detected at a substantially younger age and at substantially smaller size on average than those involving the ciliary body or choroid. Tumors that involve the ciliary body frequently interfere with the zonule or indent and displace the crystalline lens and thereby cause blurring of vision in the affected eye. Some patients with an anterior uveal melanoma will report

**Fig. 8.1.19** Nodular Pale Iris Melanoma Having Prominent Intralesional Blood Vessels.

eye pain due to shedding of melanoma cells from the tumor that clogs the trabecular meshwork, thereby causing an abrupt rise in intraocular pressure.

Iris melanoma appears as a melanotic iris tumor in most cases (Fig. 8.1.15). The tumor is usually focally nodular but can be diffuse. Most iris melanomas that have ever spawned metastasis have been larger than 5 mm in diameter and larger than 1.5 mm in thickness<sup>34</sup> (determinable by ultrasound biomicroscopy). There is considerable size overlap between larger iris nevi and smaller iris melanomas, however, and differentiation between the two is frequently impossible clinically. The tumor replaces the normal iris stroma and frequently causes the pupil to be peaked toward the lesion (most evident prior to pupillary dilation) (Fig. 8.1.16), splinted (prevented from dilating in the sector of involvement) after mydriatic drops have been administered (Fig. 8.1.17), or both. Ectropion iridis is also commonly associated with such tumors (Fig. 8.1.18). Prominent blood vessels are commonly evident within the tumor, especially if it is hypomelanotic or amelanotic (Fig. 8.1.19), and spontaneous hyphema from such blood vessels is an occasional presenting feature of such lesions. While some

**Fig. 8.1.20** Ill-Defined Darkly Melanotic Iris Melanoma Showing Discohesive Shedding of Tumor Cells That Have Become Matted in the Peripheral Iris and Angle.

**Fig. 8.1.21** Ciliary Body Melanoma Visible as Dark Retrolenticular Tumor Against Red Reflex After Pupillary Dilation.

iris melanomas remain cohesive, many become discohesive and shed tumor cells into the aqueous humor. These tumor cells can form satellite lesions by implantation on the adjacent iris stroma, become matted on the trabecular meshwork (causing elevated intraocular pressure), or both (Fig. 8.1.20).

An anterior uveal melanoma confined to the ciliary body (ciliary body melanoma) is not generally evident on slit-lamp biomicroscopy of the anterior ocular segment prior to pupillary dilation but commonly shows up as a solid dark retrolenticular mass visible in the “red reflex” of the fundus following pupillary dilation (Fig. 8.1.21). Because of its hidden location behind the iris, the typical ciliary body melanoma is at least 3 mm thick when first detected. The tumor is frequently apposed to the crystalline lens in its equatorial region, and the lens is often clouded focally adjacent to that apposition. Prominent epibulbar blood vessels are frequently evident in the sclera overlying the ciliary body tumor. Transillumination of the eye usually shows a well-defined shadow corresponding to the ciliary body tumor (Fig. 8.1.22). Ultrasound biomicroscopy confirms the solid soft tissue nature of the tumor (Fig. 8.1.23).

An anterior uveal melanoma involving both the iris and ciliary body (iridociliary melanoma) will be evident in its anterior aspect on slit-lamp biomicroscopy and gonioscopy. A characteristic feature of such tumors is

**Fig. 8.1.22** Ocular Transillumination Image Showing Dark Shadow of an Underlying Ciliary Body Melanoma.

**Fig. 8.1.23** Ultrasound Biomicroscopic Image of Anterior Ocular Segment Showing Nodular Iridociliary Melanoma.

the presence of a furrow in the iris around the anterior aspect of the tumor (Fig. 8.1.24). Iridociliary melanomas occasionally extend circumferentially around several clock hours of the anterior ocular segment to form what has been termed “ring melanoma.” A ciliary body or iridociliary melanoma will occasionally extend transsclerally through vascular or neural foramina in the anterior sclera to form one or more acquired dark episcleral patches or nodules of extrascleral tumor extension (Fig. 8.1.25).

If the clinical diagnosis is not in doubt, treatment may be undertaken without a confirmatory biopsy of the tumor, but for borderline lesions classified clinically as large anterior uveal nevus versus small iris melanoma or alternative tumor type, biopsy of the tumor by methods such as fine-needle aspiration, suction cutting of a portion of the tumor using a vitrector, or conventional incisional techniques may be used to confirm the diagnosis pathologically prior to initiating treatment.<sup>35</sup>

Management options for anterior uveal melanomas include surgical excision<sup>36</sup> (iridectomy, iridocyclectomy, or cyclectomy—usually reserved for cohesive-appearing tumors), plaque radiotherapy,<sup>37</sup> and enucleation<sup>33</sup> (usually reserved for eyes that are blind and painful, have extensive seeding of the trabecular meshwork with secondary glaucoma, or contain a tumor that involves more than one quadrant of anterior segment).

**Fig. 8.1.24** Iridociliary Melanoma Showing Retraction Furrow in Iris Along Its Anterior Margin.

**Fig. 8.1.25** Limited Anterior Transscleral Extension of Iridociliary Melanoma.

### Primary Posterior Uveal Melanoma

Posterior uveal melanomas that involve the choroid (choroidal melanomas) generally appear as dark brown to golden brown choroidal tumors. Several discrete clinical growth patterns are recognized. The most common growth pattern is the oval dome-shaped tumor (Fig. 8.1.26). The tumor generally has a base that is larger than 5 mm in largest diameter and a maximal thickness larger than 2.5 mm. Many tumors that are substantially larger exhibit this same growth pattern. In general, the thickness of such tumors tends to be approximately half the basal diameter of the tumor. The most characteristic growth pattern (albeit not the most frequent) is the *mushroom-shaped tumor* (Fig. 8.1.27). This three-dimensional shape is due to tumor eruption through Bruch's membrane to form an extruded sub-retinal nodule projecting from the dome-shaped tumor base. The eruption is frequently eccentric from the tumor base and is occasionally multifocal. The apical eruption may be relatively small compared with the tumor base, approximately the same size as the tumor base, or substantially larger than the tumor base when the tumor is detected (Fig. 8.1.28). In this latter case, B-scan ultrasonography may be performed to confirm the cross-sectional shape of the tumor. Some choroidal melanomas exhibit an irregular geographic base and one or more accentuated tumor nodules (*irregular growth pattern*) (Fig. 8.1.29), and others exhibit a broad base associated with a maximal thickness that is smaller than or equal to 20% of its largest basal diameter (*diffuse growth pattern*; Fig. 8.1.30).

**Fig. 8.1.26** Choroidal Melanoma Exhibiting Typical Smoothly Nodular Dome Shape. (A) Clinical appearance of tumor. (B) Corresponding B-scan ultrasonographic image showing bluntly biconvex cross-sectional shape and relatively low internal sonoreflectivity of tumor.

**Fig. 8.1.27** Choroidal Melanoma Exhibiting Eccentric Darkly Melanotic Eruption Through Bruch's Membrane.

Most choroidal melanomas that are left untreated for any reason (including uncertainty about the clinical diagnosis) exhibit progressive enlargement that is usually evident within 1–3 months. Smaller growing choroidal melanomas frequently exhibit prominent clumps of orange pigment (lipofuscin) on their surface (Fig. 8.1.31) as an indicator of active enlargement,<sup>38,39</sup> and most choroidal melanomas develop a serous retinal

**Fig. 8.1.28 B-Scan Ultrasonographic Images of Choroidal Melanoma That Have Erupted Through Bruch's Membrane.** (A) Tumor with small base and relatively large apical cap. (B) Tumor with a biconvex cross-sectional base and relatively large apical cap. Note that the base of each tumor is relatively hyporeflective while the apical cap is more brightly sonoreflective.

detachment over and around the tumor (Fig. 8.1.32) that increases in extent as the tumor enlarges.<sup>39</sup> This nonrhegmatogenous retinal detachment can become total and bullous in association with larger choroidal tumors. For reasons that are not obvious, some nodular choroidal melanomas enter a phase during which the tumor exhibits prominent clinical features of chronicity (numerous prominent drusen, disruption of the overlying retinal pigment epithelium [RPE] with clumping and intraretinal invasion by RPE epithelial pigment, fibrous metaplasia of the RPE overlying the tumor, absence or a minimal amount of orange pigment on the surface of the tumor, and absence or a limited amount of overlying and surrounding serous subretinal fluid)<sup>40</sup> (Fig. 8.1.33) and remain dormant for months to years or enlarge to a limited extent during such an interval.<sup>40</sup> Clinical follow-up studies of such tumors have shown them to be associated with a much lower risk of metastasis and metastatic death than are actively enlarging choroidal melanomas of similar size.<sup>40</sup> Choroidal melanomas that arise adjacent to the optic disc or extend to or around the optic disc frequently show signs of optic disc invasion or compression (Fig. 8.1.34), and those that erupt through Bruch's membrane frequently show apical retinal invasion (Fig. 8.1.35) that may be focal or extensive. Hypomelanotic choroidal melanomas frequently exhibit prominent intralesional

**Fig. 8.1.32** Nodular Mushroom-Shaped Choroidal Melanoma Associated With Partial Serous Retinal Detachment.

**Fig. 8.1.33** Dormant Choroidal Melanoma. Note prominent disruption of overlying retinal pigment epithelium with clumping and intraretinal invasion by black retinal pigment epithelial pigment.

**Fig. 8.1.34** Juxtapapillary Choroidal Melanoma Invading Optic Disc.

**Fig. 8.1.35** Choroidal Melanoma With Prominent Apical Retinal Invasion by Brown Tumor Cells.

**Fig. 8.1.36** Choroidal Melanoma That Has Erupted Through Bruch's Membrane Exhibiting Intraretinal, Subretinal, and Intravitreal Bleeding.

choroidal blood vessels that can be demonstrated well by fluorescein angiography or indocyanine green angiography. Spontaneous subretinal and intravitreal bleeding is frequently associated with tumors that have erupted through Bruch's membrane (Fig. 8.1.36) or invaded the optic disc and retina but is extremely uncommon in choroidal melanomas exhibiting the dome-shaped, diffuse, or irregular growth pattern.

Small choroidal melanomas (generally regarded as tumors  $\leq 10$  mm in diameter and  $\leq 5$  mm in maximal thickness) may be asymptomatic if they are extramacular but are usually associated with blur and flashes if located in the macula. Larger choroidal melanomas are usually associated with blur, flashes, and a recognized visual field defect corresponding to the location of the tumor and the extent of associated retinal detachment. Vitreous hemorrhage from a choroidal melanoma generally causes the symptom of dark floaters.

Posterior uveal melanomas that involve both the choroid and ciliary body (ciliochoroidal melanomas) tend to be much larger when they are first detected than those confined to the choroid. Symptomatic ciliochoroidal melanomas are frequently larger than 15 mm in largest basal diameter and larger than 8 mm in maximal thickness when first identified, whereas asymptomatic peripheral ciliochoroidal melanomas detected on routine fundus examination tend to be substantially smaller. The ora serrata is pushed centrally over the crest of the posterior uveal tumor and is therefore evident without scleral depression on indirect ophthalmoscopy (Fig. 8.1.37). Prominent dilated epibulbar blood vessels (sentinel blood vessels)

**Fig. 8.1.37** Ciliochoroidal Melanoma Displacing the Ora Serrata Centrally on Its Crest.

**Fig. 8.1.39** Nodular Darkly Melanotic Extraocular Extension of a Primary Iridociliary Melanoma.

**Fig. 8.1.38** Prominent Epibulbar "Sentinel" Blood Vessels Overlying the Anterior Portion of a Ciliochoroidal Melanoma.

**Fig. 8.1.40** Ocular Transillumination Image Showing Shadow Cast by Ciliochoroidal Melanoma.

are frequently evident over the ciliary body portion of the tumor (Fig. 8.1.38), and transscleral tumor extension develops over the anterior portion of the tumor in some cases (Fig. 8.1.39). Clinical ocular transillumination shows a dark shadow corresponding to the ciliary body extent of the tumor (Fig. 8.1.40).

Most relevant diagnostic information about the intraocular tumor (size, color, intraocular location, growth activity of the tumor, and absence versus presence and extent of invasive features) is determinable by indirect ophthalmoscopy and fundus biomicroscopy.<sup>39</sup> Documentary fundus photography is helpful for patient education about the posterior uveal melanoma and may reveal some features of the intraocular tumor not recognized during fundus examination. However, B-scan ocular ultrasonography is generally regarded as the most important ancillary diagnostic study in patients with a solid intraocular tumor of the posterior ocular segment. This imaging method confirms the soft tissue nature of the tumor, reveals its cross-sectional shape, and provides estimates of the dimensions of the tumor that supplement the ophthalmoscopic and ocular transillumination findings. It also identifies posterior scleral invasion and transscleral tumor extension (Fig. 8.1.41) when they are present and permits assessment of spontaneous vascular pulsations within the tumor during dynamic imaging.

When a melanotic choroidal or ciliochoroidal tumor is larger than 10 mm in diameter and larger than 5 mm in thickness and exhibits

**Fig. 8.1.41** B-Scan Ultrasound Image of Ciliochoroidal Melanoma Showing Nodular Posterior Extraocular Extension of Tumor.

**Fig. 8.1.42 T2-Weighted Magnetic Resonance Image of Ciliochoroidal Melanoma Showing Hypointensity of Intraocular Tumor Compared With the Bright (Hyperintense) Vitreous.**

characteristic clinical features or when a smaller melanotic choroidal or ciliochoroidal tumor exhibits prominent invasive clinical features, there is usually little if any doubt about the clinical diagnosis (unless the optical media are cloudy or opaque) and virtually no need for a confirmatory biopsy of the tumor to establish a pathological diagnosis prior to treatment. However, for tumors smaller than 5 mm in diameter and smaller than 2.5 mm in thickness, there can be considerable uncertainty about the clinical diagnosis. This doubt stems in large part from the substantial size overlap that exists between larger benign choroidal nevi and small choroidal melanomas and the substantially higher frequency of choroidal nevus than of choroidal melanoma in the general population.<sup>41</sup> In such cases, the physician managing the patient needs to inform the patient about the recognized potential benefits versus potential risks and limitations of (1) assuming the tumor to be a malignant melanoma and treating it without pathological confirmation of the diagnosis, (2) assuming the tumor to be a large benign choroidal nevus and leaving it untreated but arranging for regular periodic follow-up to monitor for active tumor enlargement, and (3) performing a diagnostic fine-needle aspiration biopsy of the choroidal tumor to establish a cytopathological diagnosis that can then be used to direct subsequent tumor management and arrange for intervention in accordance with the patient's informed decision.

In some patients with a suspected primary posterior uveal melanoma, vitreous hemorrhage, a mature cataract, or a hemorrhagic retinal detachment may preclude a satisfactory clinical view of the fundus mass. In such cases, a supplemental imaging study of the affected eye (e.g., high-resolution MRI without and with contrast) may be able to identify the tumor and characterize it as consistent or inconsistent with uveal melanoma (Fig. 8.1.42). However, in patients with clear optical media and satisfactory ophthalmoscopic evaluation of the fundus and complete ultrasonographic evaluation of the eye, such a supplemental study adds minimally to diagnostic accuracy.

Patients with primary posterior uveal melanoma are advised routinely to undergo a baseline systemic "staging" evaluation intended to identify or rule out metastatic tumors in the sites where such tumors are most likely to occur (liver, lungs, bones of the chest and abdomen, and skin).<sup>42</sup> The currently recommended evaluation consists of a general physical examination (principally to detect cutaneous metastases, jaundice, and hepatomegaly, if present), blood testing for liver enzyme levels (likely to be elevated if the liver is involved extensively), and CT scans of the chest and abdomen with contrast. In many European centers, ultrasounds of the liver are performed instead of CT scanning. In some centers, MRI of the chest and abdomen and even positron emission tomography (PET)/CT scanning are used as alternatives to CT scanning. Unless the patient has recent-onset neurological or psychiatric symptoms, baseline imaging of the brain is not recommended.

Provided that baseline systemic staging shows no worrisome lesions suggestive of metastasis, treatment is directed toward elimination or destruction of the primary intraocular tumor. The principal treatment options for posterior uveal melanoma at present<sup>26</sup> are enucleation (indicated for blind, severely painful eyes secondary to the intraocular tumor), eyes containing an extremely large intraocular tumor (generally regarded to be a tumor >16 mm in diameter, >10 mm in thickness or both), and

eyes with a circumpapillary choroidal tumor or optic disc invasion) and focal radiation therapy (the most commonly employed methods being I-125 plaque radiotherapy<sup>43</sup> and gamma knife and proton beam irradiation<sup>44</sup>) for posterior uveal melanomas smaller in size than those prompting enucleation and not invading the optic disc. These focal radiation therapy methods have been shown to yield virtually the same rate of cure as enucleation when applied to comparable, appropriately selected cases (principally posterior uveal melanomas ≤16 mm in diameter and ≤10 mm thick not involving the macula or optic disc and not associated with extrascleral tumor extension).<sup>45-47</sup> While these radiation therapy methods usually destroy the intraocular tumor and preserve the treated eye, vision in that eye is frequently impaired and may be lost completely (usually after a period of months to years) because of radiation-induced side effects on the optic disc and retina, secondary (usually neovascular) glaucoma, or both. Alternative management options employed in certain centers include transscleral en bloc tumor resection<sup>48</sup> (principally reserved for relatively young and healthy patients without retinal invasion, optic disc invasion, or macular involvement) and vitrector endoresection of the intraocular tumor<sup>49</sup> (usually performed following focal tumor irradiation to minimize the risk of intraocular dissemination or extraocular implantation of viable tumor cells during the procedure<sup>48,50</sup>). Long-duration exposure, relatively low power, large spot size transpupillary infrared laser therapy (frequently referred to as transpupillary thermotherapy, TTT) has been employed extensively in several centers to treat selected small melanocytic choroidal tumors in the large nevus versus small melanoma category over the past three decades,<sup>51</sup> but long-term studies have shown such treatment as single modality therapy to be associated with an extremely high probability of local tumor relapse and occasional instances of transscleral tumor extension to the orbit.<sup>52</sup> Because of this, TTT is not generally recommended today except as a supplement to focal radiation therapy.<sup>53</sup>

In most centers today, prognostic testing of tumor cells is performed in conjunction with treatment of the intraocular tumor in virtually all patients (unless the patient had a biopsy of the tumor prior to treatment for diagnostic or confirmatory reasons and underwent prognostic testing of the tumor cells at that time).<sup>54</sup> In patients undergoing focal radiation therapy, direct transscleral or indirect transvitreal fine-needle aspiration biopsy of the choroidal or ciliochoroidal tumor for gene expression profiling or chromosomal analysis is performed immediately prior to tumor irradiation.<sup>55</sup> In patients managed by enucleation or tumor resection, fresh tumor cells are harvested immediately after globe or tumor removal for prognostic gene expression profile testing (DecisionDx-UM test<sup>56,57</sup>) and classification (GEP class 1 [favorable], GEP class 2 [unfavorable]) or chromosomal mutation studies (e.g., multiplex ligation-dependent probe amplification,<sup>30</sup> [MLPA] or microsatellite analysis<sup>38</sup> [loss of heterogeneity testing]) and classification (disomy 3 [favorable], monosomy 3 [unfavorable]). Current evidence shows such prognostic testing to be superior to any individual clinical or histopathological factor or combination of such factors for dividing patients into relatively high risk versus relatively low risk for future emergence of distant metastasis.

Regardless of how the primary intraocular tumor was treated, the patient with a posterior uveal melanoma must be considered at risk for future emergence of metastatic tumors. Prognostic testing of the tumor cells as outlined in the preceding paragraph helps the clinician subdivide patients into those having higher versus lower risk of metastasis, and this information is currently being used in many centers to influence how frequently and how intensively (i.e., which components of a surveillance regimen are employed) a given patient is re-evaluated systemically following ocular tumor treatment.<sup>57</sup> At present, there is no adjuvant therapy that has been proven in randomized clinical trials to prevent or delay emergence of metastatic tumors compared with no treatment at all.<sup>59</sup> If a patient with primary uveal melanoma is identified as having metastatic melanoma during follow-up (either by periodic surveillance testing or by symptom-prompted testing), that patient's prognosis for long-term survival is currently poor. Although there is great current interest in targeted therapy for individual patients based on that patient's particular constellation of genetic abnormalities within the tumor cells,<sup>60,61</sup> no method of chemotherapy, immunotherapy, or molecular pathway modifier therapy has been shown to date to improve survival of patients with metastatic uveal melanoma significantly compared with no treatment at all.<sup>62</sup>

## Primary Intraocular Lymphoma

Primary intraocular lymphoma is an unusual form of malignant non-Hodgkin's lymphoma that appears to arise independently in one or both eyes of occasional individuals. Because lymphoid cells are not

present normally in the eye (except within the intravascular blood), the source of these malignant lymphoid cells is unknown.<sup>63,64</sup> Two principal clinical types of primary intraocular lymphoma are currently recognized. *Primary vitreoretinal lymphoma* is characterized by malignant lymphoid cell infiltrates, usually of B-cell lineage, involving the vitreous, retina, and subretinal pigment epithelial space of one or both eyes with limited if any involvement of the uvea.<sup>65,66</sup> This form of primary intraocular lymphoma is associated with antecedent, concurrent, or subsequent primary CNS lymphoma in approximately 80% of cases. *Primary uveal lymphoma* is characterized by focal or diffuse uveal infiltration by malignant lymphoid cells with limited involvement of the retina and vitreous in most cases.<sup>67,68</sup> This form of primary intraocular lymphoma is almost always unilateral. Approximately 30% of patients with this form of primary intraocular lymphoma ultimately develop systemic non-Hodgkin's lymphoma.

### Primary Vitreoretinal Lymphoma

The typical clinical features of primary vitreoretinal lymphoma are prominent cellular infiltrates of the vitreous (Fig. 8.1.43), geographic off-white to pale yellow accumulations of lymphoid cells under the RPE (Fig. 8.1.44), and patchy ill-defined retinal infiltrates (Fig. 8.1.45). The typical affected patient is over 60 years of age with a slight female predominance. The abnormal intraocular features are usually bilateral, although not necessarily present simultaneously, and may be substantially asymmetrical. Affected patients frequently report blur and floaters if vitreous cells are

prominent and visual blurring and field loss if retinal and subretinal infiltrates predominate. Some patients have prominent vitreous cells without retinal or subretinal infiltrates, and a few have prominent subretinal tumors or infiltrates with few if any vitreous cells. Patients may report a history of prior CNS lymphoma. Patients without such a history and their spouses or family members should be queried about recent changes in affect, slurred speech, or other neurological or psychological symptoms that might indicate undiagnosed CNS involvement. All patients with clinically suspected vitreoretinal lymphoma should be evaluated by CNS imaging (MRI or CT scanning with contrast) to identify any clinically detectable CNS lesions and lumbar puncture for CNS cytology should be performed prior to any ocular intervention in patients found to have suspicious foci in the brain on CNS imaging or exhibiting new neurological or psychological symptoms even if the CNS imaging is negative. Provided that these studies are negative, posterior vitrectomy with cytopathological and immunocytochemical analysis of the obtained intravitreal cells<sup>69,70</sup> (and lymphoid cell flow cytometry, if possible) should be performed on patients with a prominent cellular infiltration of the vitreous to establish a pathological diagnosis that can be used to direct subsequent patient evaluation and management. Occasionally, the obtained cells will be predominantly monoclonal by immunocytochemical analysis and consistent with malignant lymphoid cells cytopathologically. In such cases, most ophthalmic pathologists are comfortable classifying those cells as consistent with vitreoretinal lymphoma. Frequently, however, most of the intact cells recovered from the vitrectomy fluid appear to be mature lymphocytes rather than clearly malignant lymphoid cells and exhibit some polyclonality on immunostaining. The key to diagnosis in such cases is the presence of numerous necrotic tumor cells in the background. Necrotic cells are not a feature of inflammatory cell infiltrations of the vitreous but are an almost consistent feature in cases of lymphoma. In patients with prominent geographic subretinal pigment epithelial infiltrative tumors but few if any vitreous cells, transvitreal fine-needle aspiration biopsy can be performed to obtain tumor cells and thereby establish a pathological diagnosis.<sup>71</sup>

In cases with an established diagnosis of primary vitreoretinal lymphoma but no evident active CNS lymphoma, a course of intravitreal injections of methotrexate (typical dose per injection 400 mcg/0.1 mL) can be used to eliminate the active intraocular lymphoma.<sup>72</sup> In patients unwilling to undergo such injections or unable to return for the repeated injections in the course of treatment, low-dose fractionated external beam radiation therapy can be performed on the affected eye or eyes to eradicate the intraocular lymphoma.<sup>73</sup> Fortunately, most intraocular lymphomas respond favorably to these methods of treatment.

Patients with primary vitreoretinal lymphoma must be monitored for possible development of lymphoma in a previously unaffected eye, local relapse of vitreoretinal lymphoma in a treated eye, or development of new neurological symptoms suggestive of emerging CNS lymphoma.

**Fig. 8.1.43** Slit-Lamp Biomicroscopic Image Showing Prominent Cells in Anterior Vitreous in an Eye With Primary Vitreoretinal Lymphoma.

**Fig. 8.1.44** Widefield Fundus Image of Primary Vitreoretinal Lymphoma Showing Multiple Characteristic Geographic Subretinal Pigment Epithelial Infiltrates.

**Fig. 8.1.45** Combined Intraretinal and Subretinal Infiltrates in an Eye With Primary Vitreoretinal Lymphoma.

Patients with confirmed primary CNS lymphoma are managed currently in most oncology centers by multidrug intravenous methotrexate-based chemo-immunotherapy and intrathecal methotrexate.<sup>74</sup> Although the median survival time of patients with primary vitreoretinal lymphoma seems to be improved somewhat in recent years using such a regimen for CNS involvement, most affected patients still ultimately die of their lymphoma.

## Primary Uveal Lymphoma

Primary uveal lymphoma is characterized principally by localized or diffuse uveal infiltrates of malignant lymphoma cells, also usually of B-cell lineage. When the choroid is involved diffusely, it exhibits a diffuse creamy thickening with areas of focal accentuation (Fig. 8.1.46). A few cells are frequently present in the vitreous, and aqueous lymphoid cells and cellular deposits on the endothelium of the cornea are also present in some cases. B-scan ultrasonography of eyes with diffuse posterior uveal involvement shows diffuse thickening of the choroid (Fig. 8.1.47), sometimes in associated with a limited serous retinal detachment and crescentic hypochoic extrascleral lesions from lymphomatous proliferation. While such patients

**Fig. 8.1.46** Diffuse Creamy Thickening of Posterior Uvea With Nodular Accentuation Just Temporal to the Macula in an Eye With Primary Uveal Lymphoma.

**Fig. 8.1.47** B-Scan Ultrasound Image of an Eye With Diffuse Uveal Lymphoma Showing Generalized Choroidal Thickening and a Hypochoic, Crescentic, Retroscleral Accumulation of Tumor Cells.

are unlikely to report a prior history of CNS lymphoma or new neurological symptoms suggestive of possible CNS involvement, they are likely to report a prior or concurrent history of systemic lymphoma. If diffuse uveal lymphoma is suspected, the patient should undergo imaging of the chest and abdomen as well as baseline CNS imaging. The intraocular diagnosis can be confirmed by fine-needle aspiration biopsy<sup>71</sup> or incisional biopsy of the thickened uvea<sup>75</sup> in such patients. As long as there is no evident systemic or CNS lymphoma, the affected eye should generally be treated by low- to moderate-dose fractionated external beam radiation therapy. Treated patients should be monitored for signs of local tumor relapse or emergence of systemic lymphoma.

## MEDULLOEPITHELIOMA

Medulloepithelioma is an uncommon primary intraocular malignant neoplasm that arises from neuroectodermal cells that give rise to the epithelia of the ciliary body. The cells that comprise most medulloepitheliomas frequently appear rather bland without any pronounced nuclear pleomorphism or prominent nucleoli. The tumors that comprise medulloepithelioma are graded as benign versus malignant largely on the basis of whether the tumor has invaded and replaced adjacent tissues.<sup>76</sup>

Characteristic histopathological features of classic medulloepitheliomas are the formation of pseudorosettes composed of atypical neuroepithelial cells and the presence of associated neuroepithelial cysts containing vitreous.<sup>76,77</sup> In most cases, the tumor cells retain features of the neuroepithelium from which they arose. In some cases, however, some of the tumor cells exhibit differentiation into tissues not present normally in the eye (e.g., cartilage).<sup>78</sup> In cases such as these, the tumor is frequently classified pathologically as a “teratoid” medulloepithelioma. The tumors vary widely in terms of how atypical the component cells are. Medulloepitheliomas that exhibit substantial invasion and replacement of adjacent tissues are generally categorized as malignant, whereas those not exhibiting such features are commonly categorized as benign.<sup>76</sup> In spite of how the individual tumor is classified pathologically, medulloepitheliomas are associated with an extremely low potential to spawn metastasis or cause metastatic death.

The classic intraocular medulloepithelioma develops in the ciliary body and appears as an off-white to pink mass associated with small to relatively large neuroepithelial cysts on its surface (Fig. 8.1.48). Occasional tumors of this type arise in the iris (Fig. 8.1.49), retina, or even optic disc (Fig. 8.1.50).<sup>79</sup>

Most intraocular medulloepitheliomas occur sporadically in individuals without other known abnormalities, but occasional individuals with medulloepithelioma have been shown to be affected by constitutional mutations in the *DICER1* gene.<sup>80</sup> These individuals are at risk for development of an otherwise rare pulmonary neoplasm known as

**Fig. 8.1.48** White Ciliary Body Medulloepithelioma Having a Prominent Cystic Component.

**Fig. 8.1.49** Iris Medulloepithelioma Appears as a Pale Vascularized Iris-Angle Tumor.

**Fig. 8.1.51** Isolated Adenocarcinoma of Retinal Pigment Epithelium Appears as a Nodular Black Tumor Projecting Through the Sensory Retina Associated With Exudative Retinopathy and Intraretinal Blood.

**Fig. 8.1.50** Nodular Off-White Medulloepithelioma Arising From Optic Disc.

**Fig. 8.1.52** Adenocarcinoma of Retinal Pigment Epithelium Arising From Congenital Hypertrophy of Retinal Pigment Epithelium (CHRPE). Note the well-defined smoothly curved flat margin of underlying CHRPE lesion.

pleuropulmonary blastoma and other systemic neoplasms, often at a relatively young age.

If medulloepithelioma of the iris, ciliary body, or both is suspected when the tumor is quite small, it can be excised successfully by transscleral en bloc resection,<sup>81</sup> but most larger ciliary body medulloepitheliomas and those involving the retina and optic disc eventually (if not initially) come to enucleation.

## ADENOCARCINOMAS OF INTRAOCULAR NEUROECTODERMAL EPITHELIAL LAYERS

Primary intraocular adenocarcinomas (acquired malignant neoplasms arising from neuroectodermal tissues that exhibit pseudoglandular features histopathologically) can arise from the iris pigment epithelial layers, the neuroepithelial layers of the ciliary body, and the RPE. These tumors cannot be distinguished clinically from primary epithelial adenomas (acquired, benign tumors). Fortunately, each of these tumor types is extremely uncommon. The typical adenocarcinoma of the iris pigment epithelium appears as a progressively enlarging black tumor invading and replacing the iris stroma. The typical adenocarcinoma of the nonpigmented

ciliary epithelium appears as a white to pink tumor replacing the ciliary body, and the typical adenocarcinoma of the pigmented ciliary epithelium appears as a black tumor involving the ciliary body. The adenocarcinoma of the RPE can arise de novo from previously normal-appearing RPE or occasionally from the hypertrophied RPE cells that comprise a congenital hypertrophy of the retinal pigment epithelium (CHRPE). The isolated adenocarcinoma of the RPE<sup>82</sup> typically appears as a focally invasive dark brown to black tumor associated with surrounding hemorrhagic and exudative subretinal fluid (Fig. 8.1.51). The adenocarcinoma of the RPE arising from CHRPE<sup>83</sup> appears similar to the isolated tumor but exhibits the classic features of CHRPE in addition to the tumor nodule (Fig. 8.1.52).

If adenocarcinoma of one of these neuroectodermal layers is suspected clinically, it can sometimes be excised successfully by transscleral en bloc resection.<sup>83</sup> However, most confirmed cases have been treated by enucleation.<sup>82</sup> Fortunately, such neoplasms appear to pose minimal risk for extraocular extension and virtually no risk of metastasis.

## PRIMARY NONOPHTHALMIC MALIGNANT NEOPLASMS METASTATIC TO THE EYE

A wide variety of primary nonophthalmic malignant neoplasms can give rise to metastatic intraocular tumors that reach the eye by hematogenous dissemination. Most of the nonophthalmic malignant neoplasms that give rise to such intraocular tumors are carcinomas, and most of these are adenocarcinomas.<sup>84</sup> The most common anatomic sites of origin of the underlying primary malignant neoplasm, in decreasing order of frequency, are breast, lung, colon, other gastrointestinal sites, and kidney.<sup>84</sup> Skin melanoma occasionally gives rise to metastatic intraocular tumors,<sup>85</sup> and these tumors generally appear darker in color than those that arose from other cancer types. Some systemic malignant lymphomas also metastasize to the eye,<sup>86,87</sup> where they appear similar to metastatic carcinomas.

The most common site of intraocular involvement by metastatic tumors is the choroid,<sup>84</sup> but other intraocular tissues can be affected, including (in decreasing order of frequency) the iris, ciliary body, optic disc, retina, and vitreous.<sup>84</sup> The classic metastatic choroidal tumor appears as a round to oval off-white to golden discoid tumor having homogeneous coloration and no visible intralesional blood vessels (Fig. 8.1.53). The tumor is frequently associated with overlying and surrounding serous subretinal fluid that is out of proportion to the size of the choroidal lesion. Prominent intratumoral, intravitreal, and subretinal bleeding is extremely uncommon with most types of metastatic cancer to the eye. While some patients (approximately 20% of all cases in most reported large series of cases) exhibit multiple tumors of different sizes in one or both eyes (Fig. 8.1.54), the vast majority of patients (approximately 80%) with an intraocular metastatic tumor exhibit a single tumor in one eye at presentation (Fig. 8.1.55). The choroidal tumor in patients who were known to have their cancer prior to detection of a choroidal metastasis and were treated with systemic chemotherapy prior to their ophthalmic diagnosis frequently show partial regression of their choroidal tumor with prominent clumping of the overlying RPE on the surface of the tumor, giving the lesion a “leopard-spotted” appearance (Fig. 8.1.56).

Ultrasonography is frequently helpful in the differential diagnosis of metastatic choroidal tumors (Fig. 8.1.57). In contrast to choroidal melanomas, most metastatic carcinomas are substantially more sonoreflective (bright) internally, more likely to be broad based (Fig. 8.1.57A) in comparison with their thickness, and more likely to be multinodular (Fig. 8.1.57B).

Metastatic carcinomas to the iris<sup>88</sup> appear as white to pink, frequently irregular, discohesive tumors that have a tendency to bleed spontaneously, shed tumor cells into the aqueous humor, or both (Fig. 8.1.58). Such tumors often cause a painful abrupt rise in intraocular pressure in the affected eye.

Metastatic tumors to the optic disc<sup>84</sup> generally appear as discohesive white to pale yellow infiltrates of the disc (Fig. 8.1.59) associated with abrupt onset and progressive worsening of vision in the affected eye.

Metastatic tumors to the retina<sup>89</sup> generally appear as smudgy discohesive infiltrates, frequently associated with extravasated intraretinal blood and exudates (Fig. 8.1.60). When the source cancer for metastasis to the eye is cutaneous malignant melanoma, the intraocular tumor is more likely to be dark in color and more likely to involve the retina than the typical carcinoma metastatic to the eye (Fig. 8.1.61).

If the affected patient has other concurrent metastatic tumors more amenable to biopsy than the ocular tumor, those extraocular tumors can be sampled to confirm the diagnosis pathologically. However, if the eye is the only suspected site of involvement, fine-needle aspiration biopsy of the intraocular tumor can be performed to confirm the suspected intraocular diagnosis.<sup>90,91</sup>

Treatment of the patient depends on whether the eye is the only site of metastasis and whether one or both eyes are affected. In patients with multisystem metastasis including one or both eyes, a chemotherapy or

**Fig. 8.1.61** Primary Cutaneous Melanoma Metastatic to Retina Causing Localized Hemorrhagic-Exudative Retinopathy.

immunotherapy regimen appropriate to the primary cancer type<sup>92</sup> is typically initiated. If visual acuity is impaired as a result of the metastatic ocular disease, palliative external beam radiation therapy to the affected eye or eyes<sup>93</sup> is commonly provided. If a solitary metastatic tumor is present in only one eye, a focal destructive treatment such as I-125 plaque radiotherapy<sup>94</sup> can be used to eradicate the tumor. In recent years, some intraocular metastatic tumors have been treated successfully by intraocular injections of anti-VEGF drugs.<sup>95</sup> Unfortunately, patients who experience metastatic cancer to the eye generally have a poor prognosis for more than a few months of survival.<sup>96</sup>

## SECONDARY MALIGNANT INTRAOCULAR NEOPLASMS

Occasional patients who have a primary eyelid, conjunctival, orbital, or paranasal sinus malignant neoplasm will develop a secondary malignant

**Fig. 8.1.62** Primary Squamous Cell Carcinoma of Conjunctiva Invading Eye. Note smudgy off-white tumor cells in anterior chamber.

**Fig. 8.1.63** B-Scan Ultrasound Image Showing Diffuse Choroidal Involvement by Primary Paranasal Sinus Lymphoma That Invaded the Orbit and Eye Secondarily.

intraocular neoplasm by intraocular invasion from that adjacent site. Intraocular tumors of this type are much less common than metastatic tumors to the eye but should be recognized as a distinct category of intraocular malignant neoplasms. The conjunctival tumors most likely to invade the eye secondarily are conjunctival squamous cell carcinomas<sup>97</sup> and mucoepidermoid carcinomas<sup>98</sup> (Fig. 8.1.62). The intraocular tumor portion of the tumor is frequently obscured by the overlying conjunctival mass but can usually be demonstrated by ultrasound biomicroscopy if it is suspected clinically. The orbital tumor most likely to invade the eye is malignant lymphoma arising in the orbit or paranasal sinuses (Fig. 8.1.63).<sup>99</sup> The intraocular tumors of these types can occasionally be eliminated by trans-scleral resection or focal radiation therapy, but secondary enucleation of the affected eye is performed in many of these patients.

## HEMATOLOGICAL NEOPLASIAS INVOLVING THE EYES

Leukemias of different clinical, pathological, and cytogenetic varieties all have presence of malignant neoplastic cells in the circulating blood as a

**Fig. 8.1.64** Chronic Myelogenous Leukemia Causing Neoplastic Pseudo-Hypopyon as Initial Manifestation of Disease Relapse.

**Fig. 8.1.66** Leukemic Infiltration of Retina.

**Fig. 8.1.65** Diffuse Leukemic Infiltration of Choroid Giving Rise to Serous Retinal Detachment of the Macula. Similar Findings Were Evident in the Fellow Eye of This Patient.

**Fig. 8.1.67** Optic Disc Infiltration by Leukemic Cells.

common feature. Some of these neoplastic cells can exit the bloodstream in the eye and form infiltrative tumors in various intraocular tissues including the iris (Fig. 8.1.64), choroid (Fig. 8.1.65), retina (Fig. 8.1.66), optic disc (Fig. 8.1.67), and vitreous (Fig. 8.1.68).<sup>100-104</sup> Leukemic patients are also susceptible to secondary microbial infections attributable to impaired immunity caused by their disease or its treatment. These patients can experience endogenous retinal or subretinal abscesses and microbial endophthalmitis (Fig. 8.1.69).<sup>105</sup> Leukemic patients also tend to have impaired coagulation attributable to features of their disease including hypofibrinogenemia and absence of sufficient circulating platelets.

The most common intraocular lesions associated with leukemia are retinal hemorrhages, which tend to be multifocal and are sometime extensive (Fig. 8.1.70). Patients with forms of leukemia associated with very high white blood cell counts frequently develop dilation and tortuosity of the retinal veins and secondary macular retinal edema (Fig. 8.1.71). Some of these leukemic patients develop peripheral retinal capillary bed occlusions and subsequent peripheral retinal neovascularization with preretinal intravitreal bleeding.<sup>106</sup> Frank and sometimes bilateral retinal venous occlusions can also occur. Occasional patients with leukemia develop a serous

macular retinal detachment in each eye as a presenting clinical feature (see Fig. 8.1.65).<sup>107,108</sup> Relatively few patients with leukemia in most large series actually develop infiltrative intraocular tumors composed of leukemic cells.<sup>102</sup>

When a patient with a history of leukemia or concurrent active leukemia who appears to have infiltrative leukemic versus microbial lesions in one or both eyes is encountered, the managing ophthalmologist must advise the patient about the differential diagnosis and the potential benefits versus potential risks and limitations of (1) assuming the lesions to be leukemic and advising treatment for the presumed leukemia, (2) assuming the intraocular lesions to be microbial infiltrates and advising systemic treatment for the presumed type of infection, or (3) admitting the uncertainty of the ocular diagnosis and arranging for fine-needle aspiration biopsy or vitrectomy with cytopathological and microbiological testing of the obtained specimen to establish a definitive diagnosis that can then be used to direct subsequent patient management.<sup>105</sup> Treatment for leukemic infiltrates in the eye consists of systemic multidrug chemotherapy appropriate for the type of leukemia followed by bone marrow transplantation in patients whose leukemia can be eradicated.

# Benign Intraocular Neoplasms, Hamartomas, and Choristomas

## 8.2

James J. Augsburger, Zélia M. Corrêa, Amy C. Scheffler

**Definition:** Spectrum of intraocular tumors composed of minimally to moderately atypical but nonmalignant neoplastic cells capable of expanding to a limited extent, impairing vision of the affected eye by various mechanisms, and, depending on cell type, possibly giving rise to malignant intraocular neoplasms.

### Key Features

- Wide spectrum of tumor size, color, laterality, focality, and shape.
- Cells of origin:
  - Derived from cells that were once pluripotential.
  - Some are acquired lesions (e.g., uveal nevi, retinal astrocytomas, retinal capillary hemangiomas, circumscribed choroidal hemangiomas, choroidal osteomas).
  - Some are congenital (e.g., iris choristomas, combined hamartoma of retina).
  - The mechanism by which cells of mesodermal origin in the uveal tract give rise to bone that comprises choroidal osteomas is currently unknown.
- Growth pattern:
  - Most benign intraocular neoplasms, hamartoma, and choristomas do not exhibit growth after initial diagnosis.
  - Many lesions (larger choroidal nevi, circumscribed choroidal hemangiomas, choroidal osteomas) do enlarge to a limited extent long term.
  - Some (e.g., retinal capillary hemangiomas) enlarge progressively and achieve substantial size.
- May produce visual loss by a variety of mechanisms of visual loss including:
  - Choroidal neovascularization.
  - Macular edema.
  - Subretinal fluid.
  - Tractional retinal detachment.
  - Epiretinal membrane.
  - Vitreous hemorrhage.
  - Replacement of the normal retinal tissue.

### INTRODUCTION

A *benign intraocular neoplasm* is an acquired (noncongenital) tumor (three-dimensional mass) that develops inside an eye and is composed of slightly atypical but nonmalignant cells of a type that exists normally in the eye. A tumor of this type can enlarge, usually to a limited extent over an extended period, but has limited if any potential for malignant transformation.

An *intraocular hamartoma* is a congenital tumor composed of normal cells and nonmalignant tissue that exist normally in their intraocular location but are present in an excessive amount. This type of tumor is commonly referred to as an overgrowth of normal tissue. A tumor of this type can enlarge, usually to a limited extent during an extended period, but has an extremely limited potential for malignant transformation.

An *intraocular choristoma* is a congenital tumor composed of normal cells and nonmalignant tissue that do not exist normally in its intraocular tissue location. A tumor of this type can enlarge, usually to a limited extent during an extended period, but has virtually no recognized potential for malignant transformation.

Some noninflammatory cellular intraocular tumors (e.g., choroidal osteoma) do not fall neatly into any one of these categories but will also be discussed in this chapter.

### BENIGN INTRAOCULAR NEOPLASMS

#### UVEAL NEVUS

The uveal nevus is a benign neoplasm composed of slightly atypical but nonmalignant uveal melanocytes. This tumor is extremely uncommon in infants and young children but becomes progressively more common in older age groups.<sup>1,2</sup> Over 10% of white individuals over the age of 50 years have at least one uveal nevus in one eye. Given this frequency, the uveal nevus is unquestionably the most common primary intraocular neoplasm one encounters in humans. Once detected, the uveal nevus can enlarge to a limited extent, usually over an extended period.<sup>3</sup> Most such tumors are 1 mm or smaller in thickness, but some achieve a thickness that can be substantially larger than 3 mm.<sup>4</sup> The uveal nevus is believed to have a limited potential for malignant transformation to uveal melanoma.<sup>5,6</sup> Cytogenetically, virtually all uveal nevi exhibit mutations in genes *GNAQ* or *GNAI1*,<sup>2</sup> and these mutations are believed to be necessary for malignant transformation.<sup>7</sup>

Uveal nevi conventionally are divided into anterior and posterior subgroups. *Anterior uveal nevi* involve the iris or iris and ciliary body together, and *posterior uveal nevi* involve the choroid, ciliary body, or both.

#### Anterior Uveal Nevus

Uveal nevi of the iris or iris and ciliary body are frequently noted by the patient as a newly developed melanotic lesion of the iris. They rarely cause any visual symptoms or secondary ocular problems. The typical anterior uveal nevus is a thin bland melanotic lesion of the iris stroma that does not exhibit any prominent internal blood vessels or produce any satellite lesions or pigment dispersion (Fig. 8.2.1).<sup>8,9</sup> The classic iris nevus is 3 mm or smaller in largest basal diameter and 0.5 mm or smaller in maximal thickness. Nevi larger than 1 mm in thickness can cause limited pupillary peaking toward the lesion and limited ectropion iridis. Gonioscopy typically shows a slightly bumpy surface but limited thickness of the lesion. Ultrasound biomicroscopy can be used to measure the thickness of the tumor and determine its internal sonorefectivity, and ocular transillumination can be used to detect involvement of the anterior ciliary body.

#### Posterior Uveal Nevus

Most nevi of the choroid or choroid and ciliary body are asymptomatic and detected on routine eye examination in an adult individual.<sup>2</sup> If the nevus develops in the macular region, it can cause some visual blurring and distortion related to degeneration of the overlying photoreceptors, accumulation of limited shallow serous subretinal fluid, or (rarely) secondary choroidal neovascularization.<sup>10</sup> The typical choroidal nevus appears as a gray-brown choroidal tumor that has bland homogeneous coloration and flat margins that blend imperceptibly into the surrounding normal choroid (Fig. 8.2.2). The classic choroidal nevus is 5 mm or smaller in largest basal diameter and 1 mm or smaller in maximal thickness. Some choroidal nevi achieve substantially larger dimensions, and these nevi can be impossible to distinguish clinically from small choroidal melanomas. Benign choroidal nevi can exhibit small clumps of orange pigment (lipofuscin) on

**Fig. 8.2.1** Typical Iris Nevus Appears as Thin Melanotic Lesion Limited to Inner Surface of Iris Stroma.

**Fig. 8.2.3** Choroidal Nevus Exhibiting Numerous Surface Drusen Indicative of Chronicity and Probable Dormancy.

**Fig. 8.2.2** Typical Choroidal Nevus Appears as a Bland Localized Darkly Melanotic Choroidal Lesion  $\leq 1$  mm in Maximal Thickness.

**Fig. 8.2.4** Choroidal Nevus Exhibiting Extensive Disruption and Clumping of Overlying Retinal Pigment Epithelium. This lesion was 1.75 mm thick but shows no clumping of orange pigment or associated subretinal fluid.

their inner surface,<sup>3</sup> but prominent clumps of orange pigment visible on indirect ophthalmoscopy are rare. As mentioned above, larger choroidal nevi frequently exhibit a limited amount of shallow overlying or surrounding serous subretinal fluid that may be evident only with testing such as optical coherence tomography (OCT) or autofluorescence imaging of the fundus. However, a prominent accumulation of serous subretinal fluid over and around the tumor that is evident on indirect ophthalmoscopy is uncommon. Choroidal nevi larger than 5 mm in diameter and larger than 1 mm in thickness frequently exhibit prominent drusen on their inner surface (Fig. 8.2.3), and some exhibit degeneration of the overlying retinal pigment epithelium with clumping and intraretinal migration by black retinal pigment epithelial pigment, a whitish patch of overlying fibrous metaplasia of the retinal pigment epithelium, or both (Fig. 8.2.4).<sup>3</sup> Occasional choroidal nevi exhibit a golden orange discoloration of the marginal portion of the tumor that gives the tumor a halo-like appearance (Fig. 8.2.5). Such *halo nevi* of the choroid and nevi associated with prominent drusen and retinal pigment epithelial abnormalities generally have a favorable long-term prognosis.

B-scan ultrasonography of eyes containing a choroidal nevus typically shows the lesion as a relatively thin, moderately sonoreflective choroidal mass that has a smooth, fusiform cross-sectional shape with tapering margins that blend imperceptibly into the surrounding normal choroid (Fig. 8.2.6).

**Fig. 8.2.5** Halo-Type Choroidal Nevus Exhibiting Golden Orange Discoloration of the Peripheral Aspect of the Centrally Melanotic Lesion.

**Fig. 8.2.6 B-Scan Ultrasound Image of Slightly Elevated Choroidal Nevus.** The Tumor Appears Fusiform in Cross-Sectional Shape and Exhibits Moderately High Internal Sonoreflectivity.

**Fig. 8.2.7 Classic Melanocytoma of Optic Disc in an Asymptomatic Teenager.**

A special subtype of choroidal nevus is the melanocytoma of the optic disc.<sup>11</sup> A melanocytoma is a form of uveal nevus composed of benign magnocellular nevus cells that contain densely packed intracytoplasmic melanin granules. Such nevi occur throughout the fundus but cannot be distinguished clinically from spindle cell nevi.<sup>12</sup> For some reason, such tumors have a tendency to develop in the choroid adjacent to the optic disc or within the optic disc and grow into the substance of the disc to form a characteristic clinical lesion. The typical optic disc melanocytoma is an elevated dark brown tumor that invades the optic disc tissue, surrounds or covers the neural tissue and blood vessels of the optic disc, and causes generalized swelling of the optic disc (Fig. 8.2.7). Such tumors are commonly found in younger persons than are extrapapillary choroidal nevi and are more likely to be detected in non-white persons. Such tumors can cause an enlarged blind spot and peripheral visual field defects but rarely cause profound visual loss. They can enlarge slowly and to a limited extent, usually over many years, but appear to have extremely limited malignant potential.

The frequency of malignant transformation of uveal nevi to uveal melanomas is a subject of considerable controversy.<sup>5</sup> Many if not most ophthalmologists equate documented enlargement of a clinically diagnosed uveal nevus with malignant transformation of that lesion.<sup>6,13</sup> As mentioned earlier, however, virtually all true uveal nevi are acquired tumors and not congenital. To become evident clinically, a uveal nevus must grow. Thus, growth of a small melanocytic uveal nevus (at least that which is limited in extent and not associated with development of any clinically apparent invasive features) should not be equated with malignant transformation. To our knowledge, no case of a uveal nevus with unequivocal pathological

**Fig. 8.2.8 Retinal Astrocytoma Appears as an Off-White Inner Retinal Tumor Overlying the Retinal Blood Vessels.**

evidence of benign features determined by cytopathological or histological examination of a biopsy specimen of that tumor prior to documented enlargement has ever been shown to be a uveal melanoma following limited enlargement. At the same time, circumstantial evidence for malignant transformation comes from two histopathological series of posterior uveal melanomas in which “nevus cells” were identified at the base of the tumor in over 70% of cases.<sup>13</sup> If a tumor diagnosed as a uveal nevus enlarges enough to be reclassified as a possible uveal melanoma, biopsy of the tumor by a method such as fine-needle aspiration biopsy with cytopathological analysis and classification of tumor cells can be performed to establish a pathological diagnosis that can then be used to justify subsequent patient management.<sup>14</sup>

## RETINAL ASTROCYTOMA

The retinal astrocytoma is an acquired benign intraocular neoplasm that arises from previously normal retinal astrocytes.<sup>15</sup> This tumor is commonly referred to as retinal astrocytic hamartoma by many authors, but there is little evidence that any of these tumors are congenital in nature. There are two clinical and pathological subtypes of retinal astrocytoma: the typical retinal astrocytoma that is characteristic of tuberous sclerosis<sup>16</sup> and the isolated giant cell astrocytoma.<sup>17</sup>

The *typical retinal astrocytoma* associated with tuberous sclerosis is a localized off-white retinal tumor arising from the retinal nerve fiber layer (Fig. 8.2.8). Small tumors of this type appear as translucent patches or opalescent lesions overlying and obscuring the larger retinal blood vessels that pass beneath them. Larger tumors of this type appear as opaque white nodules that can have a lumpy surface making them appear like “rock candy” or a “white mulberry” (Fig. 8.2.9). Although such tumors can exhibit a limited retinal vascular blood supply, they do not tend to attract dilated tortuous retinal feeder and drainer blood vessels like those encountered in retinoblastoma. In individuals with tuberous sclerosis, such lesions start to appear around the end of the first decade of life and are frequently multifocal in each eye (Fig. 8.2.10).<sup>16</sup> Identical tumors that are unilateral and unifocal develop in occasional individuals who have no other clinical evidence of tuberous sclerosis. Lesions of this type tend to enlarge to a limited extent, usually over an extended period, but have limited if any malignant potential. Systemic treatment by mTOR inhibitors for tuberous sclerosis appears to reduce the likelihood and extent of growth of such retinal tumors.

The *giant cell astrocytoma* is a unilateral unifocal tumor that develops from the retina in young adult individuals, most of whom do not have tuberous sclerosis.<sup>17</sup> The tumor replaces the retina and can achieve relatively large size, frequently in association with development of a progressive nonrhegmatogenous retinal detachment (Fig. 8.2.11). Tumors of this type are frequently misdiagnosed as amelanotic uveal melanomas, and the

correct diagnosis is often not recognized until the eye had been removed and the tumor studied histopathologically.

## RETINAL CAPILLARY HEMANGIOMA

The retinal capillary hemangioma (sometimes referred to as retinal hemangioblastoma or von Hippel tumor) is an acquired benign retinal tumor composed of foamy retinal cells and a dense matrix of abnormal retinal blood vessels. This tumor is the characteristic fundus lesion of von Hippel–Lindau disease.<sup>18</sup> The typical retinal capillary hemangioma appears as a spherical bright red retinal tumor associated with prominent dilated tortuous retinal feeder and drainer blood vessels (Fig. 8.2.12). The tumor characteristically gives rise to exudative subretinal fluid that gradually involves more of the retina as the lesion enlarges (Fig. 8.2.13). In patients with von Hippel–Lindau disease, such lesions generally develop multifocally in each eye. This situation is commonly referred to as *retinal capillary hemangiomatosis*.<sup>18</sup> These tumors not only cause progressive exudative retinal detachment but somehow stimulate development of contracting vitreoretinal bands that lead to progressive tractional retinal detachment

(Fig. 8.2.14). Identical tumors that are usually unifocal and unilateral also occur sporadically in individuals without von Hippel–Lindau disease. In some patients, retinal capillary hemangiomas arise on the optic disc (Fig. 8.2.15).<sup>19</sup> In such cases, prominent feeder and drainer retinal blood vessels may not be evident.

Fluorescein angiography shows rapid filling of the feeding retinal arteriole, nearly instantaneous hyperfluorescence of the entire hemangioma, and rapid filling of the draining retinal vein (Fig. 8.2.16). The tumor typically shows intense late hyperfluorescence due to dye leakage through its walls.

If a retinal capillary hemangioma is identified when it is small (i.e., <3 mm in diameter) and not associated with a bullous exudative or tractional retinal detachment, it can be destroyed by transpupillary laser photocoagulation or transscleral cryotherapy. If a retinal capillary hemangioma is associated with an exudative but not a tractional retinal detachment, intravitreal antivascular endothelial growth factor (VEGF) drug therapy may be able to lessen the detachment and enable subsequent successful obliteration of the tumor by laser photocoagulation or cryotherapy. If the tumor is associated with a tractional retinal detachment, the most appropriate therapy seems to be endoresection of the tumor or tumors combined

**Fig. 8.2.9** Retinal Astrocytoma Exhibiting “Rock Candy” or “White Mulberry” Features.

with pars plana vitrectomy and silicone oil injection. If a retinal capillary hemangioma develops on or adjacent to the optic disc, posterior vitrectomy with endophotocoagulation or endoresection of the tumor is frequently the best method to prevent progressive exudative-tractional retinal detachment and loss of the eye.

### UVEAL LEIOMYOMA

The uveal leiomyoma is a benign acquired neoplasm that develops from cells with smooth muscle differentiation that exist within the uveal tract, most commonly in the ciliary body or iris.<sup>20,21</sup> The typical iris tumor appears as a slowly enlarging tan stromal mass that cannot be distinguished clinically from a hypomelanotic iris melanoma. The typical ciliary body tumor appears as an off-white to heterogeneously pigmented retroiridic mass evident on indirect ophthalmoscopy or fundus biomicroscopy (Fig. 8.2.17). Such tumors do not tend to attract prominent epibulbar blood vessels but

otherwise appear similar to ciliary body melanomas. Tumors of this type develop more frequently in women than in men and are usually detected in individuals in the 40–60-year-old age range.

### UVEAL NEURILEMOMA

The uveal neurilemoma is a benign acquired neoplasm that develops from the Schwann cells investing sensory fibers of the trigeminal nerve within the uveal tract.<sup>22</sup> Most tumors of this type develop in the choroid.<sup>23</sup> The typical choroidal neurilemoma appears as a discoid amelanotic choroidal tumor (Fig. 8.2.18). The retina is typically attached over and around such tumors, even ones that have attained reasonably large size. Some choroidal blood vessels can usually be visualized within such tumors, but these blood vessels do not appear to be of irregular caliber and course or grossly leaky in the way that those of primary uveal melanoma are. Most such tumors that have been encountered have been misdiagnosed as choroidal melanomas and treated as such.

**Fig. 8.2.16 Fluorescein Angiogram of Retinal Capillary Hemangioma Shown in Fig. 8.2.12.** (A) Retinal arterial filling phase frame. (B) Full retinal venous filling phase frame. (C) Recirculation phase frame.

## ADENOMAS OF INTRAOCULAR NEUROECTODERMAL EPITHELIAL TISSUES

Benign adenomas can develop from the pigment epithelium of the iris, the epithelial layers of the ciliary body, and the retinal pigment epithelium.<sup>24-26</sup> Each of these benign acquired neoplasms is extremely rare. Adenomas of the iris pigment epithelium generally appear as black nodular tumors that replace the overlying iris stroma gradually (Fig. 8.2.19). Adenomas of the retinal pigment epithelium appear as well-defined black nodular tumors underlying the sensory retina (Fig. 8.2.20). Adenomas of the ciliary epithelial layers appear white when they arise from the nonpigmented ciliary epithelium and black when they arise from the pigmented ciliary epithelium. The most common of these tumors is the adenoma of the nonpigmented ciliary epithelium (Fuchs' adenoma), which is frequently noted in autopsy eyes as an incidental finding. Most of these tumors are small and do not warrant any treatment unless they are progressive.

## INTRAOCULAR HAMARTOMAS

### CIRCUMSCRIBED CHOROIDAL HEMANGIOMA

The circumscribed choroidal hemangioma is generally categorized as a choroidal blood vessel hamartoma in spite of the fact that very few such lesions have ever been identified congenitally.<sup>27</sup> The tumor is composed entirely of a localized overgrowth of choroidal blood vessels of various calibers associated with a loose connective tissue stroma. The typical tumor appears as an oval to round discoid reddish orange choroidal mass that is located entirely posterior to the equator (Fig. 8.2.21). The posterior margin of virtually all circumscribed choroidal hemangiomas is located within 3 mm of the nearest margin of the optic disc, foveola, or both.<sup>28</sup> The classic circumscribed choroidal hemangioma is detected in individuals between the ages of 35 and 45 years, although larger tumors are more likely to be identified at a substantially younger age. The tumor is frequently

**Fig. 8.2.17** Leiomyoma of Iris (Confirmed by Postexcision Histopathology).

**Fig. 8.2.18** Choroidal Neurilemoma (Confirmed by Transscleral Incisional Biopsy).

**Fig. 8.2.19** Adenoma of the Iris Pigment Epithelium Prior to Microsurgical Excision. Note black color and cohesive character of tumor.

**Fig. 8.2.20** Focal Adenoma of the Retinal Pigment Epithelium in the Macula. Optical coherence tomography confirmed outer retinal location of tumor.

**Fig. 8.2.21** Classic Circumscribed Choroidal Hemangioma Appears as an Ill-Defined Reddish Choroidal Tumor. In virtually all cases, the posterior margin of the tumor is located within 2 disc diameters from the fovea, nearest optic disc margin, or both.

associated with a slowly progressive serous retinal detachment that can become bullous and total in some eyes with a larger tumor (Fig. 8.2.22).

Circumscribed choroidal hemangioma is generally confirmed by a combination of fluorescein or indocyanine green fundus angiography and B-scan ocular ultrasonography. Fluorescein angiography generally shows relatively rapid filling and late smudgy staining of the hemangioma (Fig. 8.2.23). Indocyanine green angiography generally shows better definition of the full extent of the hemangioma in the early to intermediate frames than does fluorescein angiography, and it also reveals late central washout of the dye that is characteristic of this type of tumor and rarely if ever encountered with other tumor types (Fig. 8.2.24). B-scan ocular ultrasonography of circumscribed choroidal hemangioma shows a fusiform to biconvex cross-sectional shape of the tumor and moderately bright internal sonorefectivity of the tumor (Fig. 8.2.25).

Photodynamic therapy is generally regarded as the treatment of choice for smaller visually symptomatic circumscribed choroidal hemangiomas.<sup>29</sup> This treatment usually gets the tumor to flatten partially and eliminates the associated serous subretinal fluid. Larger circumscribed choroidal hemangiomas associated with a bullous retinal detachment can be treated by low-dose episcleral plaque radiotherapy, proton beam irradiation, or conventional fractionated external beam radiation therapy.<sup>27</sup> This treatment induces partial flattening of the choroidal tumor and gradual reabsorption

**Fig. 8.2.22 Relatively Large Circumscribed Choroidal Hemangioma Associated With Bullous Secondary Retinal Detachment.** Note white fibrous metaplasia of the retinal pigment epithelium on the surface of the tumor.

**Fig. 8.2.26** Classic Combined Hamartoma of the Retina Appears as a Circumpapillary Retinal Lesion Having a Dark Gray Peripheral Marginal Component and Prominent Whitish Gliotic Inner Retinal Portion.

**Fig. 8.2.27** Peripheral Combined Hamartoma of Retina.

of the subretinal fluid. Fortunately, the circumscribed choroidal hemangioma has no recognized malignant potential.

### COMBINED HAMARTOMA OF THE RETINA

The combined hamartoma of the retina is a rare congenital hamartoma consisting of a focally abnormal overgrowth of disorganized retinal tissue.<sup>30,31</sup> The classic lesion appears as an irregular tumor with gray to black retinal pigment epithelial tissue at its base, whitish superficial gliosis, and angulated retinal blood vessels within the lesion (Fig. 8.2.26). Most such lesions develop on or adjacent to the optic disc, but occasional lesions with identical features have been documented in peripheral fundus locations (Fig. 8.2.27). The lesion exhibits remodeling of its shape over time but rarely enlarges to any clinically significant extent. This lesion is found most frequently in individuals with neurofibromatosis (NF) type 2 but also occurs in some persons with NF-1 and those without NF. This lesion shares many of the same clinical features as acquired vitreoretinal fibrosis due to some inciting event. Posterior vitrectomy with removal of vitreoretinal membranes causing tractional retinal detachment has been

**Fig. 8.2.28** Nodular Pink Congenital Tumor of Iris and Angle Prior to Microsurgical Resection.

reported in some individuals believed to have combined hamartoma of the retina<sup>32</sup> but is not usually beneficial in genuine cases. The principal risks of this lesion are marked visual impairment when the lesion involves the macula and its potential for clinical misdiagnosis as a choroidal melanoma or retinoblastoma, prompting enucleation. This lesion has no recognized malignant potential.

### INTRAOCULAR CHORISTOMAS

Several types of congenital intraocular choristomas have been reported, including ones consisting of lacrimal gland tissue,<sup>33</sup> thyroid gland tissue,<sup>34</sup> and brain tissue (glioneuroma).<sup>35</sup> The classic intraocular choristoma involves the iris and appears as a pink to off-white mass replacing a portion of the iris (Fig. 8.2.28). If an iris choristoma is suspected, it can be biopsied or excised to confirm the diagnosis. However, most cases have come to enucleation.

### BENIGN CELLULAR TUMORS OF UNCERTAIN CATEGORY

#### CHOROIDAL OSTEOMA

The choroidal osteoma is a benign acquired tumor consisting of mature bone that develops within the posterior choroid.<sup>36</sup> Although the presence of benign tissue of a type that does not exist normally within the choroid suggests that this tumor is a choristoma, no congenital tumor of this type has ever been documented. Most lesions of this type do not get diagnosed until the end of the first decade of life, and many are not detected until the second or third decade of life. The vast majority (approximately 90%) of such tumors occur in women, and they occur bilaterally in about 20% of cases. The typical choroidal osteoma appears as a posterior off-white to golden plate-like choroidal lesion with well-defined, smoothly curved margins (Fig. 8.2.29). Almost all documented tumors of this type involve the juxtapapillary choroid, and many extend partly or completely around the optic disc and through the fovea. The overlying retinal pigment epithelium is frequently disrupted with clumping of black pigment and patchy white fibrous metaplasia of the retinal pigment epithelium on the surface of the lesion (Fig. 8.2.30). Secondary choroidal neovascularization develops overlying many tumors of this type, with localized hemorrhagic or exudative detachment of the retina as a result.<sup>37</sup> The bony character of the tumor can be documented by ocular ultrasonography, which shows plate-like hyperreflective tissue that shadows the eye wall and orbital tissues behind

**Fig. 8.2.29 Classic Choroidal Osteoma Affecting Both Eyes of a Young Adult Woman.** Note well-defined smoothly curved margins and golden-orange color of each lesion. (A) Right eye fundus. (B) Left eye fundus.

it (Fig. 8.2.31), or CT scanning, which shows a plate of bone-dense tissue within the posterior choroid (Fig. 8.2.32).

Photodynamic therapy has been reported to cause “decalcification” of the treated portion of some choroidal osteomas but does not eliminate or prevent progression of the lesion.<sup>38</sup> Intravitreal anti-VEGF drug therapy can be used to treat secondary choroidal neovascularization with exudative-hemorrhagic retinal detachment that develops over some lesions. In most cases, the visual prognosis for the affected eye is poor. Limited, slowly progressive enlargement of choroidal osteomas has been documented by multiple examiners. Fortunately, this tumor has no recognized malignant potential.

# Non-Neoplastic Intraocular Lesions and Disorders Simulating Malignant Intraocular Neoplasms

## 8.3

James J. Augsburger, Zélia M. Corrêa, Cassandra C. Brooks

**Definition:** Spectrum of non-neoplastic lesions and disorders that are frequently mistaken for malignant intraocular neoplasms.

### Key Features

Clinical features resembling one or more of the following malignant intraocular neoplasms:

- Primary uveal melanoma.
- Extraophthalmic cancer metastatic to eye.
- Primary intraocular lymphoma.
- Retinoblastoma.

### INTRODUCTION

The lesions and disorders discussed in this chapter are all non-neoplastic lesions and disorders that (in certain clinical presentations) can be mistaken for one or more of the four intraocular malignant neoplasms listed in the Key Features. The chapter is subdivided into (1) lesions and disorders simulating malignant intraocular neoplasms of the anterior ocular segment, (2) lesions and disorders simulating malignant intraocular neoplasms of the posterior ocular segment other than retinoblastoma (i.e., posterior uveal melanoma, metastatic cancer to the posterior segment, and intraocular lymphoma), and (3) lesions and disorders simulating the different clinical forms of retinoblastoma.

### NON-NEOPLASTIC LESIONS AND DISORDERS SIMULATING MALIGNANT INTRAOCULAR NEOPLASMS OF THE ANTERIOR OCULAR SEGMENT

#### NEUROEPITHELIAL CYSTS OF IRIS AND CILIARY BODY

Neuroepithelial cysts of the iris and ciliary body are thin-walled spheres filled with clear serous fluid.<sup>1</sup> The wall can be formed by the iris pigment epithelium (IPE), resulting in a dark brown color, or by anterior ciliary body neuroepithelium (CBNE), resulting in a translucent appearance. The cause of such cysts is unknown in most cases. Neuroepithelial cysts that occur as isolated lesions without an associated underlying cause are referred to as idiopathic cysts. Three principal varieties are encountered clinically based on the site of the lesion.

**Pupillary zone cysts of the iris pigment epithelium** are evident at the pupillary margin prior to pupillary dilation. They can be solitary (Fig. 8.3.1) or multifocal (Fig. 8.3.2), in which case the term *iris flocculi* is commonly applied. They do not distort the pupil or interfere with pupillary dilation. Ultrasound biomicroscopy (UBM) or anterior segment optical coherence tomography (AS-OCT) can be used to confirm the cystic nature of these lesions. **Peripheral neuroepithelial cysts of the iris** appear as smooth anterior bulges in the peripheral iris evident on slit-lamp biomicroscopy and

**Fig. 8.3.1 Cyst of Pupillary Zone of Iris Pigment Epithelium.** (A) Color image of cyst. (B) Ultrasound biomicroscopic image of cyst shown in A.

gonioscopy (Fig. 8.3.3). The anteriorly displaced iris stroma appears unremarkable. Focal iridocorneal apposition corresponding to the location of the cyst is frequently present. Occasionally, transpupillary retroillumination of the iris at the slit lamp will reveal a faint focal transillumination defect corresponding to the cyst. Gonioscopy following wide pupillary dilation can sometimes show the smooth wall of the cyst. However, UBM and AS-OCT are the currently preferred methods for confirming the cystic lesion, as opposed to a solid tumor, as the primary cause of the iris bulge (Fig. 8.3.3B). These studies frequently reveal multiple cysts when only one

**Fig. 8.3.2 Multifocal Cysts of Pupillary Zone of Iris Pigment Epithelium (Iris Flocculi).** (A) Color image of *iris flocculi*. (B) Ultrasound biomicroscopic image of iris cysts shown in A.

was suspected on ophthalmic physical examination. **Midzonal cysts of the iris pigment epithelium** are not evident on slit-lamp examination prior to pupillary dilation but appear as a dark brown retroiridic ridge-shaped mass projecting in front of the lens when the pupil is widely dilated (Fig. 8.3.4A). The overlying iris stroma appears normal. The cyst can appear bilobed (Fig. 8.3.4B) or multilobed. Cysts of this type are commonly mistaken for ciliary body melanomas. AS-OCT or UBM confirms the cystic nature of the lesion in such cases (Fig. 8.3.4C) and rules out a solid iridic or ciliary body melanoma.

### EPITHELIAL INCLUSION CYST OF IRIS

An epithelial inclusion cyst of the iris is a thick-walled spherical or irregularly shaped structure containing relatively turbid fluid in which discrete particles are suspended.<sup>2</sup> The wall of the cyst is composed of conjunctival epithelial cells, and the intracavitary particles are desquamated ocular surface squamous epithelial cells. The ocular surface epithelium is embedded in the iris either as a congenital malformation of the eye or as a result of eye wall perforation (which may be surgical or nonsurgical trauma). This type of cyst is an off-white to bluish gray mass that replaces the iris stroma and distorts the architecture of the iris and shape of the pupil (Fig. 8.3.5A). Such lesions can be mistaken for amelanotic anterior uveal melanoma or a nonophthalmic primary malignant neoplasm metastatic to the iris. UBM shows the thick wall of the cyst and suspended intracavitary squamous epithelial cells (Fig. 8.3.5B).

### ANTERIOR SCLERAL STAPHYLOMA

In some patients with prior focal ocular injury, scleral inflammation, or ischemia, a focal area of bluish brown scleral thinning (Fig. 8.3.6) will

develop.<sup>3</sup> The intraocular pressure can cause the thinned portion of the eye wall to bulge externally. Anterior staphylomas frequently are mistaken for ciliary body melanomas with extraocular extension. Ocular transillumination generally reveals bright transillumination rather than a dark shadow corresponding to the bulge. UBM confirms thinning of the eye wall and absence of any underlying uveal or neuroectodermal mass.

### IRIDOCORNEAL ENDOTHELIAL SYNDROME

The iridocorneal endothelial (ICE) syndrome is a developmental disorder of the eye characterized by acquired nontraumatic corneal edema, progressive abnormalities of the iris, and elevated intraocular pressure.<sup>4,5</sup> Three subcategories of ICE syndrome are commonly recognized: essential iris atrophy, the iris nevus syndrome (Cogan–Reese syndrome), and Chandler’s syndrome. Only the first two of these entities are relevant to this discussion. In **essential iris atrophy**, the spontaneous development of high peripheral anterior synechiae (PAS) occurs, leading to progressive thinning with eventual hole formation of the iris 180° opposite the original adhesions (Fig. 8.3.7).<sup>5</sup> The pupil is gradually displaced toward the PAS. This condition is usually unilateral and most commonly affects middle-aged to older women. AS-OCT or UBM can be used to rule out an iridic or ciliary body melanoma. In **iris nevus syndrome**, multiple focal dark brown to almost black bumps of melanotic iris tissue develop on the anterior surface of the iris. These bumps are due to melanotic tissue projecting through small defects in an abnormal basement membrane (Fig. 8.3.8).<sup>4</sup> In most cases, the presence of shiny basement membrane tissue on the anterior surface of the iris and the multifocal nature of the iris lesions allow one to distinguish this condition from diffuse iris melanoma. AS-OCT or UBM will show absence of any solid ring melanoma of the peripheral iris or anterior ciliary body.

### INFLAMMATORY TUMOR OF IRIS OR CILIARY BODY

Occasionally individuals will develop a microbial inflammatory tumor of the iris or ciliary body (e.g., tuberculoma,<sup>6</sup> fungal granuloma<sup>7</sup>) due to hematogenous dissemination of micro-organisms to that portion of the uvea. Others will develop various nonmicrobial inflammatory tumors (most commonly sarcoid granulomas<sup>8</sup> and lesions of juvenile xanthogranuloma<sup>9,10</sup>) in the iris or ciliary body (Fig. 8.3.9). Lesions of these types are usually unilateral but can be bilateral. They are characterized by prominent inflammatory cells in the anterior chamber, keratic precipitates, posterior synechiae with resultant pupillary distortion, and occasionally hypopyon. Such inflammatory tumors can easily be mistaken for nonophthalmic primary cancers metastatic to the anterior uvea.

### IRIS FOREIGN BODY

Occasionally intraocular foreign bodies simulate an anterior uveal melanoma (Fig. 8.3.10).<sup>11,12</sup> The patient generally recalls a prior ocular injury but is frequently unaware that any foreign body perforated the eye wall. Slit-lamp biomicroscopy shows a localized mass of the peripheral iris associated with focal iridocorneal adhesion. An entry wound is frequently not evident. UBM can show the presence of a dense hyperreflective body within the mass.<sup>13</sup>

### ADVANCED CATARACT SIMULATING CILIARY BODY MELANOMA ON B-SCAN ULTRASONOGRAPHY

When B-scan ultrasonography (US) is performed on some eyes with an advanced opaque cataract and peripheral fundus imaging is attempted from across the eye, the US beam can pass through the posterior aspect of the enlarged cataractous lens and thereby form a cross-sectional image that appears to show a ciliary body mass (Fig. 8.3.11).<sup>14</sup> In most cases, the same finding can be demonstrated in all quadrants of the eye. At the same time, ocular transillumination demonstrated no ciliary body shadow and UBM demonstrates the enlarged lens.

**Fig. 8.3.3 Cyst of Peripheral Zone of Iris Pigment Epithelium.** (A) Slit-lamp biomicroscopic image showing smooth anterior bulge in peripheral iris corresponding to location of the cyst. (B) Ultrasound biomicroscopic image showing thin-walled cyst containing clear fluid. (C) Ultrasound biomicroscopic image of typical peripheral zone cyst of iris pigment epithelium.

## NON-NEOPLASTIC LESIONS AND DISORDERS SIMULATING MALIGNANT INTRAOCULAR NEOPLASMS OF THE POSTERIOR OCULAR SEGMENT OTHER THAN RETINOBLASTOMA

### CONGENITAL HYPERTROPHY OF RETINAL PIGMENT EPITHELIUM

Congenital hypertrophy of retinal pigment epithelium (CHRPE) is a non-neoplastic birthmark lesion of the fundus localized to the retinal pigment epithelium (RPE).<sup>15</sup> The RPE cells comprising this lesion are generally taller than normal and densely packed with intracytoplasmic melanin granules. The lesion has a well-defined margin and black to dark gray-brown color. Although the typical unifocal CHRPE lesion is 3 mm

or smaller in diameter, some are substantially larger (Fig. 8.3.12). Because of their dark color, larger CHRPE lesions are frequently suspected to be choroidal melanomas, particularly if a cataract is present that degrades the clarity of the fundus view. B-scan ocular ultrasonography demonstrates a flat or insignificantly elevated lesion. Rarely, one of these lesions spawns an adenocarcinoma of the RPE.<sup>16,17</sup> Because of this, such lesions should be monitored periodically.

### FOCAL RETINAL PIGMENT EPITHELIAL HYPERPLASIA

Patients who suffer blunt trauma or localized intraocular inflammation sometimes develop a localized area of RPE hyperplasia that can be somewhat thickened (Fig. 8.3.13).<sup>18,19</sup> The lesion generally appears as an irregular, poorly defined mass consisting of localized nodular accumulation

**Fig. 8.3.4 Cyst of Intermediate Zone of Iris Pigment Epithelium.** (A) Solitary cyst appearing as dark ridge-like mass between posterior surface of iris and anterior lens capsule following wide pupillary dilation. (B) Bilobed cyst of intermediate zone of iris pigment epithelium evident following pupillary dilation. (C) Ultrasound biomicroscopic image showing retroiridic cyst projecting into the pupil following pupillary dilation.

**Fig. 8.3.5 Epithelial Inclusion Cyst of Iris (Stomal Cyst).** (A) Opalescent cyst replacing portion of iris stroma. (B) Ultrasound biomicroscopic image showing thick-walled bilobed cyst containing numerous particles (desquamated epithelial cells) in the intracavitary fluid.

**Fig. 8.3.6 Anterior Scleral Staphyloma Appears as a Subconjunctival Bluish Gray Ridge-Shaped Protrusion of the Sclera.**

**Fig. 8.3.7 Essential Iris Atrophy.** The pupil is ovoid in shape and drawn toward the limbus superonasally, with prominent holes evident in the iris stroma.

**Fig. 8.3.9 Inflammatory Tumor of Iris (Sarcoid Granuloma).** Note the multiple associated keratic precipitates in this eye.

of black RPE pigment with surrounding chorioretinal atrophy. Because of its dark color, such a lesion is occasionally mistaken for a choroidal melanoma. There is usually no subretinal fluid associated with the lesion. B-scan ocular US confirms the presence of moderately hyperreflective soft tissue corresponding to the fundus lesion.

### SPONTANEOUS SUBRETINAL HEMATOMAS

Subretinal hematomas are masses composed of extravasated blood accumulated between the sensory retina and RPE or between the RPE and choroid.<sup>20</sup> The hematoma appears as a dark red to almost black subretinal mass that is usually bordered by a thin marginal zone of bright red subretinal blood. Because of its dark color and thickness, such a hematoma is frequently mistaken for a choroidal melanoma. The most common source of the blood is a choroidal neovascular membrane–associated age-related macular degeneration<sup>21</sup> (Fig. 8.3.14) or peripheral exudative-hemorrhagic chorioretinopathy (Fig. 8.3.15).<sup>22,23</sup> Choroidal neovascularization that is polypoidal in character is particularly likely to give rise to subretinal hematomas.<sup>22</sup> Chorioretinal atrophy is frequently evident adjacent to the hematoma in affected eyes, and fibrous organization of prior subretinal blood is frequently present as well. In most patients, the underlying disorder is evident bilaterally, but its clinical manifestations may be markedly asymmetrical. An alternative source of the blood that closely simulates

**Fig. 8.3.14** Massive Subretinal Hematoma Associated With Age-Related Macular Degeneration.

**Fig. 8.3.15** Massive Peripheral Subretinal Hematoma Associated With Peripheral Exudative-Hemorrhagic Chorioretinopathy.

choroidal melanoma is a retinal arterial macroaneurysm that has ruptured (Fig. 8.3.16).<sup>24,25</sup> Blood from this retinal vascular lesion generally extends not only into the subretinal space under the macroaneurysm but also into the retina and overlying vitreous. The preretinal blood frequently obscures the macroaneurysm. When the macroaneurysm is visible, it is frequently misinterpreted as a focal eruption of a choroidal melanoma through Bruch's membrane. Fluorescein angiography frequently reveals focal hyperfluorescence corresponding to the macroaneurysm that helps to identify the source of the bleeding.

### LOCALIZED SUPRACHOROIDAL HEMATOMA

Localized suprachoroidal hematomas (sometimes referred to as limited hemorrhagic choroidal detachments) are an accumulation of blood between the outer layers of the choroid and the overlying sclera.<sup>26</sup> This type of hematoma generally appears as a golden brown subretinal mass (Fig. 8.3.17) that is commonly misidentified as a choroidal melanoma. Unlike a subretinal hematoma, the localized suprachoroidal hematoma shows no marginal zone of thin bright red subretinal blood. The surface of the

**Fig. 8.3.16 Subretinal Hematoma and Intraretinal Bleeding from Ruptured Macroaneurysm of Retinal Artery.** (A) Relatively fresh lesion with bright red blood except for the subretinal hematoma under the macroaneurysm. (B) Older lesion with dark gray to off-white subretinal blood deep to macroaneurysm and dark red intraretinal blood around macroaneurysm.

mass is generally smooth and bland, and the color of the mass is generally uniform. If the hematoma has been present for several days already, a series of choroidal folds is frequently present overlying the mass. Such folds are not evident over choroidal melanomas. On fluorescein angiography, the mass shows mild choroidal hypofluorescence of its marginal zone but exhibits central isofluorescence with surrounding normal choroid. In most cases, hematomas of this type resolve completely without chorioretinal scarring within approximately 6–8 weeks.

### ACQUIRED NONFAMILIAL RETINAL HEMANGIOMATOUS LESION

A proliferation of both glial cells and retinal blood vessels that develops in the fundus periphery in response to chorioretinal ischemia or inflammation is known by a variety of names, including acquired nonfamilial retinal hemangiomatous lesion, retinal vasoproliferative tumor, and peripheral

**Fig. 8.3.17 Localized Suprachoroidal Hematoma.** (A) Wide-field image showing dark color of the hematoma. (B) Suprachoroidal hematoma exhibiting choroidal folds on its surface.

exudative hemangiomatous chorioretinal gliovascular tumor.<sup>27,28</sup> This lesion appears as an off-white peripheral chorioretinal tumor having an irregular network of retinal blood vessels on its inner surface (Fig. 8.3.18). Unlike a retinal capillary hemangioma, this tumor does not exhibit any dilated tortuous afferent or efferent retinal blood vessels. However, an exudative intraretinal and subretinal response is frequently associated with the tumor. Most lesions of this type develop in the oral zone of the fundus inferotemporally in middle-aged to older individuals. However, a substantial percentage of these lesions are more posterior in the fundus and associated with an underlying disorder such as pars planitis or retinitis pigmentosa (Fig. 8.3.19).<sup>27</sup> Although tumors of this type are not darkly pigmented, they are frequently misdiagnosed as choroidal melanomas that have erupted through Bruch's membrane in the fundus periphery.

### NODULAR POSTERIOR SCLERITIS

Nodular posterior scleritis is a nonmicrobial inflammatory disorder that affects a localized portion of the posterior sclera.<sup>29–31</sup> The eye is usually uncomfortable (achy and tender) and intensely erythematous (Fig. 8.3.20A). The lesion appears as a nodular or ridge-like posterior subretinal mass that is usually golden-brown to pale in color (Fig. 8.3.20B–C). These masses are frequently misdiagnosed as amelanotic choroidal or ciliochoroidal

**Fig. 8.3.18** Typical Idiopathic Peripheral Acquired Nonfamilial Retinal Hemangiomatous Lesion (Vasoproliferative Tumor). Note the off-white color of the tumor, presence of abnormal retinal blood vessels on the surface of the lesion, and associated subretinal exudates.

**Fig. 8.3.19** Secondary Acquired Nonfamilial Retinal Hemangiomatous Lesion Associated With Retinitis Pigmentosa.

melanomas. Marginal choroidal folds concentric to the mass are evident in many cases. A secondary serous retinal detachment is frequently associated with the lesion. The condition can usually be distinguished from choroidal melanoma by ocular B-scan ultrasonography, which confirms moderately sonoreflective fusiform thickening of the involved posterior sclera and the presence of a retrobulbar sonolucent cleft of inflammatory fluid (Fig. 8.3.20D) rather than the low internal sonoreflectivity typical of choroidal melanoma. If recognized and treated promptly by systemic corticosteroids, the mass generally shrinks abruptly and occasionally resolves completely. In contrast, if the inflammation becomes chronic before the condition is recognized or is not treated aggressively enough, the thickened sclera frequently becomes densely fibrotic and fails to shrink in response to any therapy.

## BILATERAL DIFFUSE UVEAL MELANOCYTIC PROLIFERATION ASSOCIATED WITH SYSTEMIC CARCINOMA

Bilateral diffuse uveal melanocytic proliferation associated with systemic carcinoma (BDUMPASC, frequently referred to by the abridged acronym BDUMP) is a paraneoplastic proliferation of uveal melanocytes stimulated in some way by an underlying systemic carcinoma (which may be overt or occult).<sup>32-34</sup> This uveal melanocytic proliferation commonly occurs in association with geographical or reticular clumping of orange pigment in the fundus and rapid development of an opalescent cataract bilaterally in phakic eyes. The uveal melanocytic stimulation sometimes results in development of multiple discrete melanotic uveal tumors in both eyes that can be mistaken for primary or metastatic uveal melanomas (Fig. 8.3.21A,B). In other cases, the choroid becomes thickened diffusely without any prominent multifocal or diffuse melanotic pigmentation. Such cases are more likely to be mistaken for diffuse uveal lymphoma than for primary posterior uveal melanoma. A secondary serous retinal detachment may develop in some cases (Fig. 8.3.22). The stimulatory substance and the reason certain individuals with systemic carcinoma develop this disorder have yet to be discovered. Identification and effective treatment of the underlying carcinoma can slow progression of the disorder in some patients, while plasmapheresis seems to stabilize the ocular lesions in some patients.<sup>35</sup> However, systemic corticosteroid therapy and whole-eye external beam radiation therapy appear to have limited if any value.

## VORTEX VEIN VARICOSITY

A varix (varicosity) of a choroidal vortex vein ampulla is a choroidal vascular channel that becomes distended when the patient looks in certain directions of gaze.<sup>36,37</sup> Presumably this is due to compression of the ophthalmic vein exiting the sclera in the corresponding quadrant by the belly or tendon of one of the vertical extraocular muscles. The fundus mass attributable to this localized venous distension appears as a smooth dark red tumor just posterior to the ocular equator in one of the oblique quadrants (usually superonasal or inferonasal) when the patient looks in the direction of gaze that results in ophthalmic vein compression (Fig. 8.3.23A–B). The dark color of the “mass” frequently leads to the mistaken diagnosis of choroidal melanoma. However, unlike a choroidal melanoma, the lesion flattens instantly when the patient changes direction of gaze and the extraocular venous compression is no longer present. The mass can be demonstrated by B-scan ultrasonography when the patient looks in the appropriate direction of gaze.

## ORBITAL TUMOR INDENTING EYE WALL

An orbital tumor not adherent to the globe occasionally indents the eye wall focally in such a way that an examiner perceives a localized fundus mass that may be interpreted as a choroidal melanoma or metastatic choroidal tumor.<sup>38</sup> Unlike a true choroidal malignant neoplasm, however, the position of the mass with regard to the optic disc and fovea appears to change as the patient changes his or her direction of gaze (Fig. 8.3.24A–B). Ocular ultrasonography or orbital imaging by computed tomography (CT) or magnetic resonance (MR) discloses the presence and size of the underlying orbital tumor.

## SCLEROCHOROIDAL CALCIFICATION

Sclerochoroidal calcification is a degenerative lesion that develops in the posterior sclera and underlying choroid of both eyes (sometimes very asymmetrically) in some elderly individuals who seem to be healthy systemically and in somewhat younger individuals who have abnormalities of calcium and phosphate metabolism (e.g., hyperparathyroidism).<sup>39</sup> The typical lesion appears as an ill-defined to nummular elevated pale fundus lesion (Fig. 8.3.25). A single lesion may be evident, but several lesions may be located along arcs extending from above and below the optic disc toward the fundus midline temporally just outside the superotemporal and inferotemporal retinal vascular arcades (Fig. 8.3.26A–B). Especially in this latter situation of multiple bilateral pale fundus lesions, this condition is frequently misdiagnosed ophthalmoscopically as metastatic cancer to the choroid. The retina is attached over and around the lesions. B-scan ocular ultrasonography shows dense hyperreflectivity of the lesions with shadowing of the orbital tissues behind them. CT scans of the orbit show the individual lesions to be bone dense. If there is any question about the

**Fig. 8.3.20 Nodular Posterior Scleritis.** (A) External image showing intense reddish discoloration of the sclera. (B) Fundus image showing chorioretinal folds and partial inward tilt of optic disc by ill-defined subretinal mass superonasally. (C) Ridge-like fundus mass attributed to nodular posterior scleritis. (D) B-scan ultrasonographic image showing diffuse posterior scleral thickening.

patient's calcium–phosphorus metabolism, serum levels of calcium and phosphorus should be checked as a baseline study.

### ENDOGENOUS MICROBIAL SUBRETINAL ABSCESS

Some patients with microbial sepsis develop endogenous microbial subretinal abscesses.<sup>40–45</sup> These lesions are white to yellow subretinal masses, commonly associated with prominent vitreous cells (Fig. 8.3.27), and can be mistaken for primary vitreoretinal lymphoma. Such lesions are more common in immunosuppressed individuals than in fully immunocompetent ones and often develop in individuals with chronic underlying diseases such as AIDS, cystic fibrosis, or hairy cell leukemia. The subretinal mass can expand relentlessly and destroy the eye or remain relatively localized depending on the patient's immune status. Transvitreal fine-needle aspiration biopsy or vitrector biopsy may be required to establish the microbiological diagnosis and direct antibiotic therapy.

### ATYPICAL RETINAL PIGMENT EPITHELIAL DETACHMENT

The typical RPE detachment is a localized blister-like accumulation of serous or exudative fluid between the RPE and Bruch's membrane. It

generally measures between about 1 and 3 disc diameters in basal size, but is usually no more than 1–1.5 mm in maximal height. The lesion has a smoothly biconvex cross-sectional shape and well-defined margins. Its most common location is in the macula. It typically occurs secondary to choroidal neovascularization in age-related macular degeneration<sup>46</sup> or as a manifestation of choroidal inflammation such as in Harada's disease.<sup>47</sup> On fluorescein angiography, the blister fills slowly but exhibits well-defined margins by the recirculation phase of the study. Atypical RPE detachments differ from typical ones in being substantially larger than the typical lesion<sup>46</sup> (Fig. 8.3.28) [in which case they frequently simulate either amelanotic choroidal melanoma or a metastatic choroidal tumor], hemorrhagic and therefore dark in color<sup>48</sup> (Fig. 8.3.29) [in which case they can simulate a melanotic choroidal melanoma], or multifocal<sup>49</sup> (Fig. 8.3.30) [in which case they can simulate metastatic choroidal tumors or primary intraocular lymphoma]. In spite of their atypical features, such RPE detachments retain features of their typical counterparts and therefore can usually be distinguished from malignant neoplastic lesions.

### BULLOUS CENTRAL SEROUS CHORIORETINOPATHY

Typical central serous chorioretinopathy (CSC) is a fundus disorder characterized by a central blister of serous subretinal fluid that occurs unilaterally or bilaterally in young to middle-aged men. On fluorescein angiography,

**Fig. 8.3.21 Paraneoplastic Bilateral Diffuse Uveal Melanocytic Proliferation (BDUMP) Associated With Systemic Cancer.** (A) Right eye fundus. (B) Left eye fundus.

**Fig. 8.3.22 Paraneoplastic Diffuse Uveal Melanocytic Proliferation Associated With Secondary Partial Serous Retinal Detachment.**

the blister characteristically fills slowly from a focal hyperfluorescent site at the RPE level, with fluorescein ascending within the subretinal fluid to appear in an umbrella pattern. The margins of the blister are usually somewhat indistinct on fundus biomicroscopy but appear more distinct in late fluorescein angiography images. Bullous central serous chorioretinopathy is an uncommon subtype of CSC that is associated with multiple turbid RPE detachments, giving rise to overlying and surrounding accumulations of serous subretinal fluid that can become bullous and shifting in character (Fig. 8.3.31A).<sup>50-53</sup> On fluorescein angiography, the turbid RPE detachments exhibit early nonfluorescence (due to blockage of choroidal fluorescence) but gradually increasing hyperfluorescence as the study continues (Fig. 8.3.31B). This condition is usually bilateral, but may be markedly asymmetrical in the two eyes. The turbid RPE detachments associated with this condition can simulate metastatic choroidal tumors quite closely. However, patients with this condition do not have any non-ophthalmic primary cancer capable of metastasizing.

**Fig. 8.3.23 Varicosity of Vortex Vein Ampulla.** (A) Fundus image showing vortex vein ampulla when it is distended. (B) Fundus image showing same vortex vein ampulla when it is collapsed.

### CILIOCHOROIDAL EFFUSION AND IDIOPATHIC UVEAL EFFUSION SYNDROME

Ciliochoroidal effusion (frequently referred to as choroidal detachment) is an accumulation of serous subretinal fluid between the uvea and sclera in the ciliary body and peripheral choroidal regions.<sup>54</sup> The accumulated serous fluid usually extends circumferentially around the eye, but may be evident ophthalmoscopically only in regions where it is accentuated (Fig. 8.3.32). Masses of this type are commonly misdiagnosed as amelanotic ciliochoroidal melanoma or metastatic carcinoma to the peripheral uvea. The anterior chamber angle is generally narrowed due to anterior rotation of the detached ciliary body, and intraocular pressure may be elevated (due to secondary angle closure) or low (due to reduced production of aqueous from the ciliary body). The process is frequently unilateral but can be bilateral. If the suprachoroidal fluid is bullous, several prominent lobules bounded by the vortex vein ampullae may be evident on ophthalmoscopy (Fig. 8.3.33). Secondary serous retinal detachment with shifting subretinal fluid is frequently associated with more prominent cases. B-scan ocular ultrasonography shows anechoic suprachoroidal fluid within lobules of bullous serous ciliochoroidal effusion, and UBM confirms ciliary body detachment by supraciliary serous fluid. Ocular transillumination does not show any discrete ciliary body shadow.

**Fig. 8.3.27** Microbial Subretinal Abscess Due to *Pseudomonas Aeruginosa* in a Patient With Cystic Fibrosis.

**Fig. 8.3.28** Large Retinal Pigment Epithelial Detachment With Turbid Fluid and Well-Defined Margins.

A particular subtype of serous ciliochoroidal effusion occurs in some middle-aged to older adult men, most of whom are hyperopic and have eyeballs of slightly smaller than average size. This disorder, known as idiopathic uveal effusion syndrome,<sup>55-57</sup> appears to be due to slightly thicker and denser anterior sclera than normal. The condition tends to affect both eyes but is frequently very asymmetrical at initial presentation. The ciliochoroidal effusion in this disorder tends to be chronic and associated with bullous serous subretinal fluid (Fig. 8.3.34A–B). The subretinal fluid generally shifts vigorously with changes in the patient's eye-head position. Because of the shifting subretinal fluid, which is frequently quite turbid, an underlying metastatic carcinoma to the posterior uvea or a diffuse posterior uveal melanoma may be suspected. As a consequence of the serous retinal detachment, the affected eye tends to develop extensive disruption of the RPE with multifocal RPE clumping (Fig. 8.3.34C), especially in the inferior hemisphere of the fundus. Ocular axial length measurement typically confirm a slightly smaller than average eyeball size, and ultrasound biometry frequently shows slightly thicker than average sclera in the ciliary body region. This condition usually responds favorably to excision of relatively thick lamellar scleral rectangles behind the level of the insertions of the rectus muscles to the equatorial region of the eye in each quadrant.<sup>56</sup>

**Fig. 8.3.29** Hemorrhagic Retinal Pigment Epithelial Detachment. Note Dark Color of This Lesion Compared to Fig. 8.3.28.

**Fig. 8.3.30** Multifocal Retinal Pigment Epithelial Detachments.

## MULTIFOCAL BEST VITELLIFORM RETINAL DYSTROPHY AND VITELLIFORM PARANEOPLASTIC RETINOPATHY

Best vitelliform retinal dystrophy is an autosomal dominant disorder characterized in its typical form by development of a central macular lesion resembling an egg yolk.<sup>58</sup> The macular lesion appears to be an accumulation of lipofuscin on Bruch's membrane that elevates and causes secondary degeneration of the RPE and outer segments of the sensory retina. The macular lesions generally become apparent by the second half of the first decade of life. The disorder has been linked to mutations in the *VMD2* (hBEST1) gene. Atypical forms include cases with late onset of the macular lesion<sup>59</sup> and ones with multiple extramacular vitelliform lesions<sup>60</sup> (Fig. 8.3.35). In this latter situation, the pale color of the individual lesions, the multiplicity of lesions, and the bilaterality of the process frequently lead to the mistaken initial diagnosis of metastatic carcinoma to the choroid.

Vitelliform paraneoplastic retinopathy is an extremely uncommon fundus disorder characterized by abrupt development of multiple discrete

**Fig. 8.3.31 Bullous Central Serous Chorioretinopathy.** (A) Color image showing smudgy subretinal lesion superior to optic disc and secondary serous retinal detachment. (B) Fluorescein angiography frame highlighting subretinal fluid in this case.

orange subretinal lesions scattered about the posterior fundus in a patient with an underlying systemic cancer.<sup>61</sup> The individual lesions resemble the lesions of multifocal Best disease but tend to be of variable sizes and slightly more irregular shape than those of classic Best disease (Fig. 8.3.36). Patients commonly report flickering lights and progressive blurring or dimming of vision in both eyes. The fundus lesions of this disorder are likely to be misdiagnosed as metastatic tumors to the choroid, at least initially.

### MASSIVE GLIOSIS OF RETINA

A benign non-neoplastic tumor composed principally of proliferated retinal glial cells occurs in some eyes in response to prior retinal inflammation or injury. These tumors are generally off-white in color and irregular in contour. When such a proliferation gives rise to a three-dimensional tumor, it is referred to as **massive gliosis of the retina**<sup>62</sup> (Fig. 8.3.37). If the lesion is relatively small (e.g.,  $\leq 5$  mm in largest linear dimension), it is commonly referred to as *focal retinal gliosis*.<sup>63</sup> In contrast, if the lesion involves an extended portion of the fundus, it is commonly referred to as

**Fig. 8.3.32 Choroidal Detachment (Ciliochoroidal Effusion) Having a Solitary Accentuated Lobule.**

*diffuse retinal gliosis*.<sup>63</sup> Lesions of these types can be misdiagnosed as retinoblastoma if they are identified in children and as amelanotic choroidal melanomas if detected in adults.<sup>64</sup>

### INFLAMMATORY CHORIORETINAL GRANULOMA

Inflammatory chorioretinal granulomas appear as golden to yellow choroidal or outer retinal nodules with overlying vitreous cells in the acute phase and clumping of RPE pigment on its surface or around its margin in the chronic phase (Fig. 8.3.38).<sup>65–69</sup> These lesions can develop in individuals of any age. In most cases, such lesions are unilateral and unifocal, but bilateral multifocal lesions occur in some patients. Such a lesion can simulate a metastasis to the choroid by a nonophthalmic primary cancer or an infiltrate of primary intraocular lymphoma quite closely. Biopsy of the lesion by a method such as fine-needle aspiration biopsy may be necessary to rule out these malignant neoplasms.

### HARADA'S DISEASE

Harada's disease is an inflammatory chorioretinal disorder that is generally believed to be an autoimmune condition.<sup>70,71</sup> It is characterized in its acute phase by vitreous cells and frequently by development of multiple foci of serous retinal detachment due to turbid subretinal fluid (Fig. 8.3.39A,B). The disorder is commonly associated with a variety of acquired cutaneous abnormalities (e.g., vitiligo, poliosis) and various neurological abnormalities (e.g., Vogt-Koyanagi-Harada disease). The majority of cases are bilateral and seen in individuals between the ages of 20 and 50 years. Harada's disease is much more common in women and people of Asian, Middle Eastern, or Native American descent. When multifocal serous retinal detachment and vitreous cells are prominent features, Harada's disease can be misdiagnosed as primary vitreoretinal lymphoma.<sup>72</sup> When multifocal serous retinal detachment is evident but vitreous cells are not, the condition can be mistaken for a nonophthalmic primary malignant neoplasm metastatic to the choroid.

### IDIOPATHIC UVEITIS IN THE ELDERLY

Idiopathic posterior uveitis is characterized by diffuse accumulation of intravitreal cells as an inflammatory response to unknown antigens. Most cases respond to systemic corticosteroid therapy or various immunomodulatory drugs. When idiopathic posterior uveitis develops in a patient over the age of 50 years, the condition is frequently suspected to be primary vitreoretinal lymphoma.

**Fig. 8.3.33 Annular (Circumferential) Choroidal Detachment (Ciliochoroidal Effusion).** (A) Fundus image centered on macula of left eye showing a peripheral ridge-like fundus elevation nasally, temporally and superiorly. (B) Fundus image centered just superonasal from optic disc showing the ora serrata on the crest of the ciliochoroidal ridge nasally, superonasally and superiorly.

### VITILIGINOUS (BIRDSHOT) CHOROIDITIS

Vitiliginous choroiditis, sometimes referred to as birdshot chorioretinopathy, is an inflammatory chorioretinal disorder of unknown cause that tends to affect older individuals (the same age group commonly affected by primary vitreoretinal lymphoma) preferentially.<sup>73,74</sup> This disease is characterized by development of multiple small round depigmented chorioretinal foci, most commonly in the inferior midzone of the fundus in both eyes, in association with the accumulation of pale vitreous cells (Fig. 8.3.40A–B). This disorder is strongly associated with HLA-A29 positivity and is frequently suspected of being primary vitreoretinal lymphoma.

### ENDOGENOUS ENDOPHTHALMITIS

Various microbes (e.g., bacteria, fungi, parasites) that enter the bloodstream from a nonophthalmic site of infection can give rise to endogenous (hematogenously disseminated) endophthalmitis in one or both eyes.<sup>44,75</sup> The onset of the condition tends to be abrupt and relentlessly progressive over a very short time. The condition is most frequently encountered in older debilitated persons and those whose systemic immunity is impaired (e.g., patients with HIV infection). When multifocal choroidal or subretinal

**Fig. 8.3.34 Uveal Effusion Syndrome.** (A) Wide-angle image showing peripheral choroidal detachment. (B) Wide-angle image showing secondary serous retinal detachment inferiorly. (C) Localized fundus image showing characteristic clumping of retinal pigment epithelium in this disorder.

**Fig. 8.3.35 Multifocal Best Vitelliform Retinal Dystrophy in Left Eye.** The image shows a small central macular vitelliform lesion and two slightly larger vitelliform lesions superior and superotemporal to the fovea.

infiltrates are prominent features, the condition can be mistaken for a non-ophthalmic primary malignant neoplasm metastatic to the choroid. When vitreous cells and retinal infiltrates are prominent features, this condition can simulate primary vitreoretinal lymphoma.

### NON-NEOPLASTIC INTRAOCULAR LESIONS AND DISORDERS SIMULATING INTRAOCULAR RETINOBLASTOMA

The differential diagnosis of retinoblastoma includes a number of non-neoplastic lesions and disorders that are not usually represented in lists of pseudo-malignant neoplasms of the uvea. These lesions and disorders affect infants and young children in the typical age range for initial diagnosis of retinoblastoma. Most cases of retinoblastoma are diagnosed correctly by experienced ocular tumor specialists, but certain forms of retinoblastoma (e.g., diffuse infiltrating retinoblastoma, anterior retinoblastoma, advanced endophytic retinoblastoma with prominent vitreous seeding, or advanced exophytic retinoblastoma associated with a total bullous retinal detachment) can pose diagnostic challenges even to experienced examiners. In the following paragraphs, several non-neoplastic lesions and disorders that can simulate different clinical presentations of retinoblastoma are discussed.

**Fig. 8.3.36 Paraneoplastic Vitelliform Chorioretinopathy.** (A) Right eye fundus. (B) Left eye fundus.

**Fig. 8.3.40 Vitiliginous Chorioretinopathy.** (A) Posterior fundus appearance. (B) Inferior fundus appearance.

### NON-NEOPLASTIC LESIONS AND DISORDERS SIMULATING INTRARETINAL RETINOBLASTOMA

The typical intraretinal retinoblastoma appears as a translucent to opaque white retinal tumor nodule fed and drained by prominently dilated and tortuous retinal blood vessels. Tumors more than about 3 mm in diameter frequently exhibit foci of intralesional calcification. Retinal astrocytoma (isolated or associated with tuberous sclerosis) is the neoplastic lesion most frequently mistaken for intraretinal retinoblastoma. The following non-neoplastic lesions and disorders can also simulate discrete intraretinal tumors of retinoblastoma.

#### VITREORETINAL TOXOCARA GRANULOMA

Occasional individuals develop an inflammatory vitreoretinal granuloma as a manifestation of endogenous ocular toxocariasis.<sup>76,77</sup> The white vitreo-retinal lesion, typically found in young children, is characteristically located at the optic disc or in the fundus periphery (Fig. 8.3.41A–B). The

lesion is generally associated with prominent vitreoretinal membranes and inflammatory cells in the vitreous. The mass does not exhibit intralesional calcification or any dilated–tortuous associated retinal blood vessels.

#### EXTENSIVE MYELINATION OF RETINAL NERVE FIBER LAYER

In normal ocular development, the nerve fibers in the nerve fiber layer of the retina are not myelinated. However, occasional eyes that are otherwise normal develop focal or patchy myelination of the retinal nerve fiber layer as a developmental anomaly.<sup>78,79</sup> In rare instances, the myelination becomes so extensive that it involves a substantial portion of the posterior retina (Fig. 8.3.42).

#### CHORIORETINAL COLOBOMA

A chorioretinal coloboma is a congenital anomaly of the choroid and retina in which the developing optic cup does not fuse completely and a developmental defect of the retina and choroid becomes evident.<sup>80,81</sup> The typical

**Fig. 8.3.41 Toxocara Vitreoretinal Granuloma in Right Eye.** (A) Color fundus photo centered just temporal to optic disc (hidden by vitreoretinal and subretinal fibrosis) showing elevated white mass just nasal to disc. (B) Color image of same lesion centered on the elevated white preretinal mass.

lesion appears as a well-defined absence of choroid and RPE and maldevelopment of the associated sensory retina in the inferior to inferonasal quadrant of the fundus (Fig. 8.3.43). The spectrum of chorioretinal coloboma is broad, ranging from limited areas of fundus involvement between the optic disc and fundus periphery, involvement of the optic disc and inferior juxtapapillary fundus only, to extended involvement of the inferior fundus that also encompasses the optic disc. Unilateral and bilateral cases have been identified.<sup>82</sup>

### TOXOPLASMIC RETINITIS

Congenital ocular toxoplasmosis frequently gives rise to a fundus lesion resembling a congenital chorioretinal coloboma.<sup>83,84</sup> Unlike the classic fundus coloboma, this lesion is usually located in the macula, is associated with prominent clumping of black RPE pigment along its margins, and is frequently bilateral (Fig. 8.3.44). Due to the white appearance of the central portion of the lesion and its detection in infants and young children, it can

**Fig. 8.3.42 Extensive Myelination of Retinal Nerve Fiber Layer.**

**Fig. 8.3.43 Chorioretinal Coloboma.**

be mistaken for retinoblastoma. However, the flat nature of the lesion and absence of any associated feeder and drainer retinal blood vessels generally allows for appropriate diagnosis of this lesion.

Acquired retinal toxoplasmosis in its typical form appears as a fuzzy white focus of active retinitis with overlying vitreous inflammatory cells.<sup>83,84</sup> If the lesion is a reactivation of a prior lesion, black RPE hyperplasia is typically evident adjacent to the lesion. Atypical multifocal toxoplasmic retinal lesions are encountered occasionally as acquired foci of retinitis in immunosuppressed individuals (Fig. 8.3.45A–B).<sup>45</sup> If the underlying condition responsible for the immunosuppression is leukemia, the multifocal retinal lesions of acquired toxoplasmic retinitis can be mistaken for leukemic retinal infiltrates.

**Fig. 8.3.44** Macular Lesion of Congenital Ocular Toxoplasmosis.

### FOCAL RETINAL GLIOSIS

As mentioned earlier (see Massive Retinal Gliosis), occasional focal lesions of this type appear as localized off-white retinal lesions that can be mistaken for viable intraretinal retinoblastoma or spontaneously arrested retinoblastoma (retinoma).<sup>63</sup> In most cases, there is a history of prior ocular injury or severe intraocular inflammation that led to development of the retinal lesion.

### LESIONS AND DISORDERS SIMULATING EXOPHYTIC RETINOBLASTOMA

Retinoblastoma is classified as exophytic if the intraretinal tumor expands preferentially from the outer aspect of the sensory retina and causes a surrounding nonrhegmatogenous retinal detachment. In these cases the tumor frequently sheds viable tumor cells into the subretinal fluid (subretinal tumor seeds). If the serous retinal detachment becomes bullous and the subretinal fluid becomes turbid, the tumor responsible for the retinal detachment may not be obvious on ophthalmoscopy. In most cases, the exophytic tumor can be detected unequivocally by ocular ultrasonography, CT scanning, or MR imaging. However, the following lesions and disorders are frequently mistaken for advanced intraocular retinoblastoma associated with a bullous retinal detachment.

### ADVANCED COATS' DISEASE

Coats' disease is an eponym applied to advanced cases of idiopathic retinal telangiectasis.<sup>85</sup> In this disorder, peripheral and sometime midzonal retinal blood vessels (which may be predominantly capillaries, venules, arterioles, or a combination) develop multiple focal fusiform or saccular expansions as a limited developmental disorder, which is almost always limited to one eye. The cause of this disorder is unknown, but it is much more common in males than in females. The abnormally dilated (ectatic) retinal blood vessels lack the tight intercellular junctions and supporting pericytes and thus lack the normal blood–retina barrier capability. These vessels can leak a protein- and lipid-containing exudative fluid that accumulates in the adjacent retina and underlying the retina. If the abnormal blood vessels are limited in extent in the fundus, the amount of accumulated exudative fluid tends to remain localized. These cases tend to be asymptomatic and are detected later in life (usually during the teenage years). In contrast, if the abnormal blood vessels involve more than one clock hour of the fundus, they frequently lead to an exudative retinal detachment of the portion of the retina containing the ectatic blood vessels and accumulation of intraretinal and subretinal exudates in the central macula (exaggerated macular exudative response) (Fig. 8.3.46). When the abnormal retinal

**Fig. 8.3.45** Acquired Multifocal Toxoplasmic Retinitis in Patient With Prior Leukemia in Remission Following Chemotherapy and Bone Marrow Transplantation. (A) Right eye fundus. (B) Left eye fundus.

blood vessels involve more than 6 clock hours of the fundus, the exudative retinal detachment frequently becomes total and bullous (Fig. 8.3.47A–B). These cases are likely to become apparent within the first 2–3 years of life. While limited forms of idiopathic retinal telangiectasis are generally easy to diagnose, advanced idiopathic retinal telangiectasis (Coats' disease) simulates exophytic retinoblastoma quite closely.<sup>86,87</sup> Ocular ultrasonography, CT scanning, and MR imaging all confirm the total retinal detachment in such cases but fail to show any solid underlying retinal tumor that is present in retinoblastoma.

### PERSISTENT HYPERPLASTIC PRIMARY VITREOUS (PERSISTENT FETAL VASCULATURE)

Persistent hyperplastic primary vitreous (PHPV), also referred to in recent years as persistent fetal vasculature (PFV), is a developmental disorder of the eye characterized by failure of regression of the embryological intravitreal and perilental vasculature, proliferation of fibroblasts associated with that vasculature, and ultimately impairment of normal ocular growth.<sup>88,89</sup> The condition is usually monocular. In its complete form, it is

**Fig. 8.3.46 Exaggerated Macular Exudative Lesion of Coats' Disease Simulating Intraretinal Retinoblastoma.**

characterized clinically by a smaller eye on the affected side (Fig. 8.3.48A), a dense retrolenticular fibrovascular mass that pulls the ciliary processes centripetally (Fig. 8.3.48B), and a fibrovascular stalk extending from the retrolenticular fibrovascular mass to the optic disc that is usually evident on B-scan ocular ultrasonography. The retina is frequently malformed, the anterior chamber is shallower than normal, and iris blood vessels are frequently noted to extend across the pupillary margin into the perilenticular fibrovascular mass (Fig. 8.3.48B). A progressive secondary cataract usually develops. This condition is frequently misdiagnosed initially as advanced exophytic retinoblastoma.<sup>90</sup>

### CONGENITAL RETINAL DYSPLASIA

Congenital retinal dysplasia is an anomalous maldevelopment of the retina in which the developing retina becomes totally detached and balled up behind the developing lens.<sup>91</sup> The condition appears as a dense white retrolenticular mass that precludes any view of the fundus in a newborn infant (Fig. 8.3.49). The condition is frequently unilateral but can be bilateral in individuals with Norrie's disease. The location of the mass behind the lens rather than more posteriorly in the eye and the lack of intratumoral calcification help to make the diagnosis. In some cases, biopsy of the retrolenticular mass is performed to rule out retinoblastoma pathologically.

### ADVANCED RETINOPATHY OF PREMATUREITY (RETROLENTAL FIBROPLASIA)

Retinopathy of prematurity (ROP) is a developmental disorder of the retinal vasculature that occurs in infants born prematurely, prior to full vascular development of the retina.<sup>92</sup> The condition is virtually always bilateral but can be substantially asymmetrical. The spectrum of this disorder is extremely broad, ranging from congenital avascularity of the peripheral retina with a well-defined vascular-avascular interface to total fibrotic retinal detachment that simulates advanced intraocular retinoblastoma (Fig. 8.3.50).<sup>93</sup> This advanced form of ROP is commonly known as retrolental fibroplasia (RLF). While this condition was once quite common, it is relatively infrequent today except in regions of the world with limited access to regular screening and treatment.

### ADVANCED FAMILIAL EXUDATIVE VITREORETINOPATHY (FEV)

Familial exudative vitreoretinopathy is a hereditary vitreoretinal disorder that closely resembles ROP but occurs bilaterally in infants and children who were born full-term.<sup>94</sup> The condition is usually transmitted as

**Fig. 8.3.47 Advanced Coats' Disease.** (A) Total bullous retinal detachment behind lens. (B) Visible telangiectatic retinal blood vessels within the detached retina.

an autosomal dominant condition. Mutations of several genes, mostly on chromosome 11, have been linked with this disorder. In its advanced form, one or both eyes develop a total retinal detachment that resembles retrolental fibroplasia and can be misdiagnosed as exophytic retinoblastoma.

### ADVANCED INCONTINENTIA PIGMENTI RETINOPATHY

Incontinentia pigmenti is an X-linked dominant developmental retinal disorder that also resembles ROP.<sup>95</sup> The disorder is attributable to a mutation of the *NEMO IKBKG* gene (chromosomal locus Xq28). The condition is almost always fatal to affected males, so almost all clinically affected infants are female. In addition to the eye abnormalities, affected individuals develop a characteristic blistering of the skin (evident from birth to about 3–4 months of age) that resolves followed by development of widespread dermal melanotic pigmentation (usually evident after about 6 months of age) that gives the condition its name (Fig. 8.3.51). In its advanced form, one or both eyes develop a total retinal detachment that resembles retrolental fibroplasia.

**Fig. 8.3.48 Persistent Hyperplastic Primary Vitreous (Persistent Fetal Vasculature).** (A) External view showing small cornea and leukocoria of affected esotropic right eye. (B) Anterior segment image of affected eye showing dense retrolenticular membrane, ciliary processes pulled centrally into the fibrovascular mass, and iris blood vessels extending across pupil into retrolenticular mass.

## LESIONS AND DISORDERS SIMULATING ENDOPHYTIC RETINOBLASTOMA

Retinoblastoma is classified as endophytic if the intraretinal tumor expands preferentially from the inner aspect of the sensory retina, becomes matted on the inner surface of the retina, and sheds viable tumor cells into the vitreous (vitreous seeds). If the vitreous seeds are particularly dense, the underlying retinal tumor may not be obvious on ophthalmoscopy. In most cases, the endophytic tumor can be detected unequivocally by ocular ultrasonography, CT scanning, or MR imaging. However, the following lesions and disorders can be mistaken for advanced endophytic retinoblastoma.

### PARS PLANITIS (INTERMEDIATE UVEITIS)

Pars planitis (intermediate uveitis) is an intraocular inflammatory disorder of unknown cause characterized by diffuse vitreous cells most prominently in the peripheral vitreous (Fig. 8.3.52A), and “snowbank” infiltrates that develop on the pars plana and peripheral retina in the oral zone. These occur most commonly inferiorly in both eyes (Fig. 8.3.52B).<sup>96</sup> Most affected eyes develop chronic cystoid macular edema. Advanced cases can simulate endophytic retinoblastoma with extensive vitreous seeding or diffuse infiltrating retinoblastoma.<sup>97</sup>

**Fig. 8.3.52 Pars Planitis (Intermediate Uveitis).** (A) Snowball opacities in vitreous. (B) Inferior peripheral snowbank of pars planitis.

### ENDOGENOUS ENDOPHTHALMITIS SIMULATING ENDOPHYTIC RETINOBLASTOMA

Acquired systemic infection of immunocompetent young children by parasites such as *Toxocara canis*,<sup>76,77</sup> *Toxoplasma gondii*,<sup>45,83</sup> and other organisms<sup>98</sup> occasionally leads to hematogenously disseminated (endogenous) intraocular infection that stimulates a pronounced intraocular inflammatory response. The disorder can be unilateral or bilateral. It is characterized by a dense accumulation of intravitreal inflammatory cells and frequently leads to generalized retinal deterioration. In children with congenital or acquired immunodeficiency, various microbes that are usually of limited virulence can give rise to a similar clinical picture that can also resemble endophytic retinoblastoma.

# Phakomatoses

James J. Augsburger, Zélia M. Corrêa

8.4

**Definition:** Group of multisystem syndromes that have characteristic ophthalmic manifestations:

- Neurofibromatosis type 1 (von Recklinghausen's disease) and type 2 (central neurofibromatosis).
- Tuberous sclerosis.
- von Hippel–Lindau syndrome.
- Sturge–Weber syndrome.
- Wyburn–Mason syndrome.

## Key Features

- Inherited in an autosomal dominant fashion (neurofibromatosis, tuberous sclerosis, and von Hippel–Lindau) or sporadic and nonheritable (Sturge–Weber syndrome and Wyburn–Mason syndrome).
- Multisystem disorders associated with characteristic intraocular lesions (uveal or retinal) and central nervous lesions that in some cases may be life threatening.
- Underlying genetic defects, when present, are not treatable but in instances ocular disease or complications are treatable.

## INTRODUCTION

The phakomatoses are a group of complex multisystem disorders linked, at least in a historical sense, by various attributes of the component lesions, the organs involved, and the pattern of clinical inheritance observed in some cases. Although the term phakomatoses was coined by van der Hoeve in 1923 in a paper concerned with the similarities between von Recklinghausen's neurofibromatosis (NF) and Bourneville's tuberous sclerosis (TS), this term has never been defined satisfactorily. Absolute inclusion criteria were not presented by van der Hoeve,<sup>1</sup> and a consensus about such criteria has not been reached in the years since. Some authors define the phakomatoses as neurocutaneous syndromes characterized by autosomal dominant inheritance.<sup>2</sup> Others define them as neurocutaneous syndromes associated with ocular lesions regardless of their inheritance pattern.<sup>2,3</sup> Still others define them as syndromes characterized by the presence or development of multiorgan hamartomas.<sup>4</sup> Ophthalmologists commonly regard the phakomatoses as neuro-oculo-cutaneous syndromes that have prominent or characteristic ocular manifestations.

For the purposes of this chapter, the authors of this chapter define the phakomatoses as a group of independent clinical syndromes characterized by multiple tumors or tumor-like lesions, some of which are or can become malignant and arise in disparate organs of the body, including the eye in a substantial proportion of patients. Three syndromes are consistently classified as phakomatoses by most authors and also meet our definitional criteria: neurofibromatosis (NF), tuberous sclerosis (TS), and von Hippel–Lindau syndrome (VHL). Two other syndromes are classified as phakomatoses by many authors but do not conform precisely to our definition: Sturge–Weber syndrome (SWS) and Wyburn–Mason syndrome (WMS). These five syndromes are reviewed briefly in this chapter. Other syndromes that are occasionally grouped with the phakomatoses by some authors (e.g., Louis–Bar syndrome [ataxia telangiectasia], Weskamp–Cotlier syndrome [retinal-neuro-cutaneous cavernous hemangioma syndrome], PTEN [phosphatase and TENsin homolog gene] hamartoma-tumor syndrome, and PHACE [posterior fossa malformations, hemangioma, arterial anomalies, cardiac defects, and eye anomalies] syndrome) are not reviewed in this chapter.

## NEUROFIBROMATOSIS

The syndrome of neurofibromatosis (NF) consists of three distinct genetic diseases with considerable phenotypic overlap.<sup>5</sup> All are characterized by neuroectodermal tumors that arise within multiple organs and autosomal dominant inheritance. The three forms of NF are termed NF-1, NF-2, and schwannomatosis.

## EPIDEMIOLOGY AND PATHOGENESIS

Neurofibromatosis is the most common phakomatosis, having a frequency of approximately one case per 2000–3000 persons in the general population.<sup>5</sup> NF-1 is by far the more common of the two types, affecting approximately one person per 2500–3000 in the general population. In contrast, NF-2 affects no more than one person per 40 000–50 000 persons. Schwannomatosis is the least common of these disorders, affecting no more than one person per 60 000–70 000 persons. Men and women appear to be affected with equal frequency, and there is no racial predilection for any of the types of the disease. Many features of these syndromes do not appear until late childhood or early adulthood. The severity of the syndrome varies markedly from patient to patient. Many patients who have limited forms of NF are probably not identified.

The gene for NF-1 has been localized to chromosome 17q11.2,<sup>6</sup> that for NF-2 has been localized to chromosome 22q12.2,<sup>7</sup> and that for schwannomatosis has been linked to an alternative region of chromosome 22 encompassing the *SMARCB1* and *LZTR1* genes (chromosome 22q11.21–11.23).<sup>8</sup>

## EXTRAOPHTHALMIC MANIFESTATIONS

Neurofibromatosis type 1 (peripheral NF, von Recklinghausen's disease) is characterized by cutaneous café-au-lait spots (Fig. 8.4.1), axillary and inguinal freckling, Lisch nodules of the iris (Fig. 8.4.2), several types of cutaneous neurofibromas, optic nerve gliomas (Fig. 8.4.3), and neurofibromas or other solid neoplasms of the central nervous system (CNS).<sup>5,9,10</sup> The café-au-lait spots (see Fig. 8.4.1) in this syndrome tend to be multiple. Many are larger than 0.5 cm in diameter in childhood and enlarge to 1.5 cm in diameter by the postpubertal years. Six or more café-au-lait spots larger than 1.5 cm in diameter in postpubertal individuals are generally

**Fig. 8.4.1** Prominent Café-Au-Lait Spot of Skin in a Patient With Neurofibromatosis Type 1.

**Fig. 8.4.2 Lisch Nodules of Iris in Neurofibromatosis Type 1.** Similar Multiple Iris Nodules Were Evident in the Fellow Eye.

**Fig. 8.4.3 Optic Nerve Glioma Causing Proptosis in Girl With Neurofibromatosis Type 1.** (A) Clinical photo showing proptosis and slight downward displacement of the left eye. (B) Reconstructed sagittal magnetic resonance imaging of left orbit showing optic nerve tumor causing proptosis.

considered diagnostic of NF-1. Axillary freckling and inguinal freckling are present in 90%–95% of affected individuals. Subcutaneous neurofibromas in NF-1 tend to arise multifocally and can be either pedunculated nodules or diffuse plexiform lesions. CNS neurofibromas can cause hemiparesis, hemiatrophy, and seizures in some affected individuals. Because of bone abnormalities related to the syndrome, some individuals develop severe scoliosis. About one half of all patients affected by NF-1 have some sort of learning disability, but most are of normal intelligence. In older patients, systemic hypertension appears to be more frequent than it is in the general

**Fig. 8.4.4 Magnetic Resonance Image Showing Bilateral Acoustic Neuromas in a Patient With Neurofibromatosis Type 2.**

population. Comprehensive clinical criteria for diagnosis of NF-1<sup>10</sup> and recommendations for genetic testing of individuals suspected of having this disorder<sup>5</sup> have been published and should be consulted by clinicians desiring such information.

Neurofibromatosis type 2 (central NF) is typified by bilateral vestibular schwannomas (acoustic neuromas) (Fig. 8.4.4) and widely scattered neurofibromas, meningiomas, gliomas, and schwannomas.<sup>5,11,12</sup> The most consistent extraophthalmic problem suffered by patients affected by NF-2 is sensorineural deafness caused by the vestibular schwannomas. Comprehensive clinical criteria for diagnosis of NF-2<sup>11,12</sup> and recommendations for genetic testing of individuals suspected of having this disorder<sup>5</sup> have been published and should be consulted by clinicians desiring such information.

Schwannomatosis is also characterized by scattered schwannomas but not ones involving the vestibular nerve.<sup>5,13</sup> Comprehensive clinical criteria for diagnosis of schwannomatosis<sup>13</sup> and recommendations for genetic testing of individuals suspected of having this disorder<sup>5</sup> have been published and should be consulted by clinicians desiring such information.

## OCULAR MANIFESTATIONS

Ophthalmological findings in NF-1 include Lisch nodules of the iris (see Fig. 8.4.2), subcutaneous pedunculated and plexiform neurofibromas of the eyelids, optic nerve gliomas (see Fig. 8.4.3), multifocal choroidal freckles or nevi (Fig. 8.4.5), and occasionally retinal tumors indistinguishable from the retinal astrocytomas found in tuberous sclerosis.<sup>14,15</sup> Lisch nodules have been described as melanocytic hamartomas of the iris stroma. These lesions appear as tan to light brown nodules that stud the iris surface (see Fig. 8.4.2). They are rarely present at birth but tend to develop by the second to third decade of life in over 95% of persons who have NF-1.<sup>16</sup> Histopathologically, Lisch nodules consist of closely packed dendritic or spindle-shaped melanocytes within the anterior layers of iris stroma. Because these cells are normal uveal melanocytes and not nevus cells, these lesions are not true nevi. Neurofibromas of the eyelids can be either nodular or plexiform in nature. They tend to develop early in life and can enlarge progressively. Gliomas of the optic nerve develop in 10%–15% of affected patients.<sup>17</sup> They can occur unilaterally or bilaterally

**Fig. 8.4.5 Multiple Melanocytic Choroidal Freckles in the Fundus of a Patient With Neurofibromatosis Type 1.** The fellow eye contained a similar number of discrete choroidal freckles.

and frequently involve the optic chiasm. Optic nerve gliomas in the orbit (see Fig. 8.4.3) can cause progressive proptosis and optic atrophy and frequently result in unilateral or bilateral blindness. Those that arise within the brain and involve the chiasm can cause bilateral visual loss as well as intracranial mass effects. Some patients affected by NF-1 have pulsating exophthalmos caused by anomalous development of the sphenoid bone. Congenital and infantile glaucomas appear to be common in patients who have this syndrome. Some affected patients develop multifocal choroidal melanocytic freckles or nevi bilaterally (see Fig. 8.4.5). Individuals with NF-1 appear to have an increased cumulative lifetime risk for development of a uveal melanoma.<sup>18</sup>

Ophthalmological findings in NF-2 are relatively uncommon.<sup>3,9,10,14</sup> Lisch nodules of the iris, eyelid neurofibromas, and optic nerve gliomas occur occasionally but are not generally present. The most consistent ocular findings in patients who have NF-2 are combined hamartomas of the retina<sup>19</sup> (described and illustrated in Chapter 8.2) and juvenile posterior subcapsular or cortical lens opacities. To date, no recurring eye abnormalities have been associated with schwannomatosis.

## SYSTEMIC MANIFESTATIONS

Detailed recommendations for systemic evaluation of patients who have suspected NF-1 or NF-2 have been published.<sup>5,9-12</sup> For patients who have suspected NF-1, the basic diagnostic evaluation should consist of a complete history and comprehensive physical examination, including an ophthalmic examination. Ancillary studies such as computed tomography (CT) and magnetic resonance imaging (MRI) should be performed in NF-1 if the history or findings revealed by physical examination suggest that they might be helpful. For patients who have suspected NF-2, the basic diagnostic evaluation should consist of a complete history and physical examination, including an ophthalmic examination and high-resolution MRI or CT imaging of the brain and spinal cord. The imaging studies should address the presence or absence of vestibular schwannomas. Other studies in suspected NF-2 are obtained as indicated by the findings detected during the basic evaluation.

## TREATMENT

Treatment of optic nerve gliomas in NF is covered in Chapter 12.10, and treatment of neurofibromas of the eyelids is covered in Chapter 12.7. Treatment of the intracranial lesions of NF-1 and NF-2 is beyond the scope of this book.

## COURSE AND OUTCOMES

Life expectancy is reduced substantially in patients who have NF-1 or NF-2.<sup>5,9-11</sup> The principal causes of early death in persons who have NF-1

**Fig. 8.4.6 Ash Leaf Spots of the Skin in a Patient With Tuberous Sclerosis.**

are complications of systemic hypertension, cancer, and expansive growth of benign intracranial neoplasms. Several types of cancer, including neurofibrosarcoma, other sarcomas, leukemias, and lymphomas, occur with increased frequency in patients who have NF-1. In patients with NF-2, the main cause of early death is expansion of a CNS neoplasm. Unilateral or bilateral blindness occurs in some individuals affected by NF-1 or NF-2, usually because of glioma of the optic nerves or chiasm (especially in NF-1) but occasionally because of expansile intracranial growth of a vestibular schwannoma or an apoplectic episode (NF-2).

## TUBEROUS SCLEROSIS

Tuberous sclerosis (TS) is a multiorgan tumor syndrome that is characterized by multifocal bilateral retinal astrocytic hamartomas, astrocytic tumors of the CNS, several unusual cutaneous lesions, mental retardation, seizures, and a variety of cysts and tumors of other organs.<sup>20</sup> The clinical spectrum is extremely broad and ranges from minimal to marked in affected individuals. Many persons who have limited forms of the disease are probably not recognized as having TS.

## EPIDEMIOLOGY AND PATHOGENESIS

The prevalence of TS in the general population has been estimated to be approximately one case per 10,000 persons.<sup>20</sup> About one third of cases are familial and two thirds are sporadic. No recognized racial predilection exists, and the sexes are affected equally. Signs and symptoms of TS usually begin by the time the patient is 6 years of age.

TS genes have been identified on loci on the long arm of chromosome 9 (9q32-34), on the long arm of chromosome 11, on the short arm of chromosome 16 (16p13), and on the long arm of chromosome 12 (12q22-24).<sup>21</sup> Of these loci, the 9q32-34 locus has been the most consistent, being associated with between one third and one half of all familial cases.

## EXTRAOPHTHALMIC MANIFESTATIONS

The characteristic extraophthalmic clinical features of TS are congenital and acquired skin lesions, benign CNS astrocytomas, and a variety of cysts and tumors that occur in organs such as the kidney, heart, and lungs.<sup>20,22</sup> The cutaneous lesions characteristically associated with TS include ash leaf spots, adenoma sebaceum, shagreen patches, and subungual and periungual fibromas. Ash leaf spots (Fig. 8.4.6) are congenital white or hypomelanotic skin macules ranging in size from about 1 mm to several centimeters in diameter and having a configuration that resembles an ash leaf. These lesions usually show up prominently when the skin is viewed under ultraviolet light. Adenoma sebaceum (Fig. 8.4.7) is an unusual facial dermatological eruption characterized by pinhead to pea-sized yellowish to reddish brown papules distributed in a butterfly fashion over the nose, cheeks, and nasolabial folds in teenagers to young adults. Histopathologically, the

**Fig. 8.4.7 Adenoma Sebaceum of Face in a Patient With Tuberous Sclerosis.**

**Fig. 8.4.8 Computed Tomography Scan of Brain Showing Paraventricular and Intracerebral Astrocytomas in a Patient With Tuberous Sclerosis.**

individual skin lesions are angiofibromas. The shagreen patch is a thickened patch of skin with the texture of pigskin or sharkskin that is usually located on the lower back. Subungual and periungual fibromas are benign fibrous tumors that develop under and at the sides of the nail beds in some patients. The CNS tumors that occur in TS are generally low-grade astrocytomas. These CNS lesions can become calcified and detectable on skull radiographs, but they are revealed much more effectively by CT or MRI (Fig. 8.4.8).<sup>20</sup> Complications associated with such lesions include mental deficiency and seizures, both of which can range from mild to severe. Many individuals who have TS have normal intellectual abilities. The most common visceral tumor that occurs in TS appears to be the angiomyolipoma of the kidney. Probably the most distinctive visceral tumor in TS is the benign cardiac rhabdomyoma. In some patients who have TS, an unusual lung disease (pulmonary lymphangioleiomyomatosis) develops.

In addition, benign cysts develop multifocally in various visceral organs, including the kidneys, liver, and lungs, in many patients who have TS.

## OCULAR MANIFESTATIONS

The typical ophthalmological feature of TS is the retinal astrocytoma (astrocytic hamartoma).<sup>23</sup> Lesions of this type are described in detail and illustrated in Chapter 8.2. Approximately one half of all patients affected by TS develop at least one retinal astrocytoma in one eye. In individuals who have TS and develop retinal astrocytomas, multiple lesions in both eyes occur in 40%–50% of cases. Malignant transformation of retinal astrocytomas occurs in TS but is rare.

## SYSTEMIC EVALUATION

Systemic evaluation of individuals for whom TS is suspected should include fundus examination, dermatological evaluation to identify characteristic skin lesions, CT or MRI of the CNS, and CT or MRI of the abdominal viscera.<sup>20,22</sup> Examination of family members to look for a familial pattern is also appropriate. Genetic testing usually is performed in suspicious cases to confirm the presence of one or more of the gene mutations associated with this disorder.<sup>21</sup>

## TREATMENT

Treatment of affected individuals with TS has changed from symptomatic management of the various lesions associated with the disorder to medical therapy of affected individuals using a variety of mTOR inhibitors to suppress development of the CNS and systemic tumors or prevent their progression.<sup>24</sup> Periodic physical examination and imaging of the CNS and abdominal–thoracic viscera by CT or MRI are appropriate to identify and monitor potentially treatable problems such as cardiac rhabdomyomas, cysts and tumors of the kidney, and enlarging CNS astrocytomas.

## COURSE AND OUTCOME

Historically, life expectancy of individuals who have TS has been reduced substantially compared with that expected in the normal population.<sup>20</sup> The most common cause of early death in this syndrome is renal failure secondary to angiomyolipomas, cysts, or both.<sup>25</sup> The second most common cause of death is obstructive hydrocephalus or other CNS problems caused by enlargement of one or more of the CNS astrocytomas. Other important but less frequent causes of death are cardiac conduction defects and heart failure from cardiac rhabdomyoma and chronic pulmonary insufficiency associated with lymphangioleiomyomatosis of the lung. In patients who have profound mental retardation and severe seizures, death occurs occasionally as a result of status epilepticus or pneumonia.

## VON HIPPEL–LINDAU SYNDROME

The von Hippel–Lindau syndrome (VHL) is a multiorgan disorder characterized by retinal capillary hemangiomas, CNS hemangioblastomas, various solid and cystic visceral hamartomas and hamartias, and malignant neoplasms, including renal cell carcinomas and pheochromocytomas.<sup>26–29</sup> The full-fledged syndrome commonly runs in families that have a clear autosomal dominant inheritance pattern. Affected individuals are at substantial risk of early death, usually because of their intracranial hemangiomatous lesion or renal cell carcinoma.

## EPIDEMIOLOGY AND PATHOGENESIS

VHL is a rare disorder, having a cumulative lifetime incidence of approximately 1 in 30 000–40 000 persons.<sup>30</sup> In patients who have full-fledged VHL, one or more clinically identifiable manifestations of the disease are usually present by or before the third decade of life. The median age at detection of the first clinical features of VHL is 20–25 years.<sup>26–29</sup> Capillary hemangiomas of the retina (described and illustrated in Chapter 8.2) are usually the earliest detected manifestation of VHL (probably because they are easiest to detect at a small size), whereas CNS hemangioblastomas typically appear slightly later and renal cell carcinomas substantially later in life. However, the timing of clinical emergence of the various lesions in individual patients who have VHL varies greatly. The cumulative probability of developing retinal capillary hemangiomas and CNS hemangioblastomas in a patient who has VHL is more than 80%, and the probability of

**Fig. 8.4.9** Computed Tomography Scan of Head Showing Cystic Cerebellar Hemangioblastoma in von Hippel-Lindau Syndrome. Note cerebellar tumor and increased intraocular density ipsilaterally (related to advanced retinal capillary hemangiomatosis causing phthisis bulbi).

**Fig. 8.4.10** Computed Tomography Scan of Abdomen of a Patient With von Hippel-Lindau Syndrome Showing Bilateral Renal Cell Carcinoma.

developing renal cell carcinoma is more than 60%. VHL affects both sexes equally and occurs in all racial groups.

As mentioned earlier, VHL is inherited as an autosomal dominant disorder in affected families. Molecular biological studies have localized the VHL gene to chromosome 3p25-26.<sup>29,31</sup>

## EXTRAOPHTHALMIC MANIFESTATIONS

Important extraocular features of VHL include hemangioblastomas (capillary hemangiomas) of the brain (Fig. 8.4.9) and spinal cord, renal cell carcinoma (Fig. 8.4.10), pheochromocytoma, several other less common solid neoplasms and related lesions, and cystic lesions of various visceral organs.<sup>26-29</sup> The typical CNS lesions of VHL are solid and cystic cerebellar hemangioblastomas (see Fig. 8.4.9), which occur in about 40% of affected individuals by the age of 30 years and in about 70% of them by the age of 60 years. The component cells in these tumors appear benign by histopathological criteria. Similar vascular lesions also occur in the medulla and spinal cord in 10%–15% of patients who have VHL.

Renal cell carcinoma is an acquired malignant neoplasm of the kidney that occurs in about 5% of VHL patients by the age of 30 years but in more than 40% by the age of 60 years. The renal cell carcinomas that occur in VHL (see Fig. 8.4.10) are bilateral in approximately 75% of cases. This tumor can metastasize, so it must be recognized early and treated aggressively if a fatal outcome is to be avoided. Other visceral neoplasms that

develop in some patients who have VHL include pheochromocytoma, islet cell carcinoma of the pancreas, and cyst-adenomas of the pancreas and epididymis. Also, those affected by VHL have a strong tendency to develop multifocal cysts in the kidneys, pancreas, and ovaries. Unlike NF and TS, VHL does not have dermatological lesions as part of the syndrome.

## OCULAR MANIFESTATIONS

The characteristic ocular lesion of VHL is the retinal capillary hemangioma,<sup>26-29</sup> which is described in detail and illustrated in Chapter 8.2. Approximately 50%–60% of patients who have VHL develop retinal capillary hemangiomatosis during their lifetimes, and about one half of these individuals have multiple retinal capillary hemangiomas in both eyes.

## SYSTEMIC EVALUATION

As a result of the frequency and severity of the various multiorgan lesions in VHL, a comprehensive baseline evaluation and periodic re-examination and ancillary testing of patients suspected of having the disease is appropriate.<sup>26-29</sup> The baseline evaluation should include genetic testing of a peripheral blood specimen to identify or rule out the presence of a deletion or mutation of the VHL gene (located on chromosome 3p25-26). The baseline systemic evaluation should include MRI of the CNS and abdomen to identify or rule out identifiable tumors and fundus examination to identify or rule out retinal capillary hemangiomas. The frequency and intensity of follow-up evaluations are dependent on the absence versus presence and extent of the abnormalities evident on the baseline evaluation and the age of the patient at the time of that evaluation.<sup>30</sup> Management of VHL must be multidisciplinary and address the specific lesions that occur in each individual patient.

## TREATMENT

Signs and symptoms of VHL and the necessity for treatment depend on the nature of the lesions that are present, the location and size of these lesions, and the symptoms that result from these lesions.<sup>30</sup> Treatment of retinal capillary hemangiomas is covered in Chapter 8.2. Treatment of the CNS and visceral lesions of this disease is generally surgical and beyond the scope of this book.

## COURSE AND OUTCOMES

Progression of retinal capillary hemangiomas in VHL is highly variable, but tumor enlargement, intraretinal and intravitreal bleeding, exudation, gliosis, and retinal detachment may develop. These complications can result in profound visual loss or even phthisis bulbi of one or both eyes. Fortunately, ophthalmic treatment is usually able to preserve good vision in at least one eye. If the associated renal tumors and intracranial vascular tumors are not detected at an early stage or are not controlled by aggressive intervention, they commonly prove fatal to the affected individuals.<sup>26-29</sup> Consequently, the life expectancy of patients who have VHL is reduced considerably compared with that of unaffected persons in the general population. The median age at death in patients who have VHL is 45–50 years in most series.

## STURGE-WEBER SYNDROME

Sturge-Weber syndrome (SWS) is a dermato-oculo-neural syndrome characterized by cutaneous facial nevus flammeus in the distribution of the branches of the trigeminal nerve, ipsilateral diffuse cavernous hemangioma of the choroid, and ipsilateral meningeal hemangiomatosis.<sup>32</sup> The lesions in the eye, skin, and brain are always present at birth (i.e., they are birthmarks or congenital anomalies rather than acquired neoplasms such as those that occur in the three syndromes already covered in this chapter).

## EPIDEMIOLOGY AND PATHOGENESIS

The frequency of the complete SWS and its formes frustes is approximately one case per 50,000 persons.<sup>32</sup> Men and women appear to be affected equally. No recognized racial predilection occurs. The vast majority of patients affected by SWS have sporadic nonfamilial disease. Only a few familial clusters of the syndrome have been reported, and most of these have not exhibited the clear-cut autosomal dominant inheritance pattern that typifies NF, TS, and VHL.

## EXTRAOPHTHALMIC MANIFESTATIONS

The classical cutaneous feature of SWS is the facial nevus flammeus (Fig. 8.4.11), a flat to moderately thick zone of dilated telangiectatic cutaneous capillaries lined by a single layer of endothelial cells in the dermis. The lesion is usually unilateral and most frequently involves the regions of the face innervated by the first, occasionally the first and second, and rarely all three branches of the trigeminal nerve. The ipsilateral nasal and buccal mucosa is involved in some patients, and localized hypertrophy of the involved tissues may be present. The characteristic CNS manifestation of SWS is ipsilateral leptomeningeal hemangiomas, which causes atrophy of the cortical parenchyma of the brain, seizures, and frequently mental retardation. The CNS lesions are present at birth and are detectable by MRI or CT (Fig. 8.4.12).<sup>33</sup> These lesions tend to be progressive throughout life.<sup>34</sup> In many patients, the affected meninges become irregularly calcified during life, in which case the CNS vascular lesion can be detected on routine skull radiographs.

## OCULAR MANIFESTATIONS

The classical ocular manifestation of SWS is the diffuse choroidal hemangioma.<sup>32,35</sup> This lesion is a generalized thickening of the choroid by mature blood vessels of various sizes. It is almost always present at birth but frequently becomes accentuated during the first two decades of life. Because the diffuse choroidal hemangioma gives the entire posterior choroid a saturated red color (Fig. 8.4.13A), it is frequently not evident on routine ophthalmoscopy, but comparing the affected fundus to the contralateral fundus (see Fig. 8.4.13) usually reveals a much more saturated red color

on the affected side, absence of any distinctly visible large caliber choroidal blood vessels on the side of the hemangioma, and deep ipsilateral cupping of the optic disc (which is frequently due to the abnormal thickness of the circumpapillary choroid but may also be due to secondary glaucomatous cupping). The generalized choroidal thickening caused by a diffuse choroidal hemangioma is better appreciated by B-scan ocular ultrasonography (Fig. 8.4.14) than by ophthalmoscopy. Other ocular abnormalities that are found in some patients who have SWS include telangiectasia of the conjunctiva and episclera (Fig. 8.4.15) and ipsilateral congenital, infantile, or juvenile glaucoma. Many eyes affected by diffuse choroidal hemangioma develop a secondary serous retinal detachment that can cause profound visual loss if not recognized and treated appropriately.

## SYSTEMIC EVALUATION

Because patients affected by SWS do not have any recognized propensity to develop benign or malignant neoplasms, they do not require periodic systemic or CNS screening tests for such lesions. However, patients who have SWS and develop seizures or progressive mental deterioration probably need periodic neurological evaluation and intermittent evaluation by CT or MRI of the brain to rule out treatable lesions or disorders.<sup>32,33</sup> Regular ophthalmological evaluations are appropriate in all patients who have

**Fig. 8.4.11 Facial Nevus Flammeus in a Patient With Sturge-Weber Syndrome.**

**Fig. 8.4.12 Computed Tomography Scan of Brain in a Patient With Left-Sided Facial Nevus Flammeus and Ipsilateral Diffuse Choroidal Hemangioma.** Note the extensive leptomeningeal hemangioma involving the left side of the brain.

(B) Unaffected left eye fundus showing visible large caliber choroidal blood vessels and physiological optic disc cupping.

**Fig. 8.4.14** Axial B-Scan Ultrasound Image of an Eye With Diffuse Choroidal Hemangioma Showing Generalized, Moderately Sonoreflective Thickening of the Posterior Choroid and Deep Focal Posterior Pit Corresponding to Optic Disc.

**Fig. 8.4.15** Episcleral Telangiectasis Ipsilateral to Facial Nevus Flammeus and Diffuse Choroidal Hemangioma in a Patient With Sturge-Weber Syndrome. This is the same patient shown in Fig. 8.4.11.

suspected or confirmed SWS to screen for treatable ocular complications such as glaucoma and serous nonrhegmatogenous retinal detachment.<sup>35</sup>

## TREATMENT

Treatment of patients who have SWS is generally symptomatic and directed toward complications caused by the vascular lesions of the brain and eyes.<sup>32</sup> Seizures are treated medically unless that therapy proves unsuccessful. Intractable seizures and progressive mental deterioration are sometimes treated surgically by techniques such as subtotal hemispherectomy.<sup>36</sup> The facial nevus flammeus can be treated by dermatological laser therapy. This treatment frequently results in marked regression of the vascular birthmark and substantial cosmetic improvement. Treatment of the ophthalmic lesions and complications of SWS include medical and surgical treatments for glaucoma and photodynamic therapy or low-dose external beam or plaque radiotherapy for nonrhegmatogenous retinal detachment secondary to the hemangioma.<sup>35</sup> Unfortunately, the visual prognosis for affected eyes is usually quite poor.<sup>37</sup>

## COURSE AND OUTCOME

The life expectancy of patients who have SWS appears to be reduced substantially compared with that of persons in the general population.<sup>32,34</sup> However, most early deaths occur in individuals who have profound mental retardation and intractable seizures and not in those who have a limited form of the disease, normal intellectual ability, and no seizures. The visual outcome of eyes affected by diffuse choroidal hemangioma depends on the thickness of the hemangioma (especially in the macula), the presence, extent and duration of secondary nonrhegmatogenous retinal detachment prior to its detection, the response of the hemangioma and the retinal detachment to photodynamic therapy or radiation therapy, and the presence and severity of secondary glaucoma in the affected eye.<sup>37</sup>

**Fig. 8.4.16** Moderately Complex Arteriovenous Malformation of Posterior Retina Superotemporally in a Patient With Wyburn-Mason Syndrome.

**Fig. 8.4.17** Complex Arteriovenous Malformation of Retina in a Patient With Wyburn-Mason Syndrome.

## WYBURN-MASON SYNDROME

Wyburn-Mason syndrome (WMS) is characterized by arteriovenous malformations (AVMs) of the retina (Figs. 8.4.16 and 8.4.17) and ipsilateral CNS (Fig. 8.4.18).<sup>38,39</sup> Because the abnormal lesions are not distinct tumors but rather anomalous arteriovenous communications and because this disorder is not associated with any characteristic skin lesions, this syndrome is not a true phakomatosis by the definition used herein. Most patients who have WMS have unilateral, nonfamilial disease.

## EPIDEMIOLOGY AND PATHOGENESIS

This syndrome is very uncommon. The retinal and intracranial AVMs of WMS are congenital. However, they are usually incompletely developed at

**Fig. 8.4.18** Computed Tomography Scan of Head Showing Prominent Arteriovenous Malformations of Brain, Orbit, and Facial Soft Tissues on the Right in a Patient With Wyburn–Mason Syndrome.

birth but progress during growth and aging.<sup>40</sup> Consequently, the vascular malformations in the retina and CNS are often undetected until the second through fourth decades of life. The more extensive the congenital vascular lesions, the earlier the presentation in most patients.<sup>38,39</sup> Men and women appear to be affected equally. No racial predilection occurs. No hereditary pattern has been identified.

## EXTRAOPHTHALMIC MANIFESTATIONS

In patients with WMS, complex AVMs occur in the orbit, the periorbital soft tissues and bones, and the midbrain ipsilateral to the retinal AVM.<sup>33,34</sup> When they are prominent, they can frequently be demonstrated by CT scanning or MR imaging (see Fig. 8.4.18), but when they are small, arteriography may be needed to image them. Not all patients who have a retinal AVM have or develop extraretinal AVMs, and only those who have both retinal and CNS AVMs should be considered to have WMS. In general, the more complex the retinal vascular anomalies, the higher the likelihood of associated CNS AVMs.<sup>38</sup>

## OCULAR MANIFESTATIONS

The classical ophthalmic abnormality of WMS is the AVM of the retina (see Figs. 8.4.16 and 8.4.17).<sup>38,39</sup> The characteristic finding is the presence of one or more retinal arterioles that enter the retina at the optic disc,

extend a variable distance away from the disc, and connect to a draining vein without any interposed capillary bed. The efferent and afferent limbs of the malformation tend to be dilated and tortuous, and the severity of dilation and tortuosity of these vessels is proportional to their respective calibers. The transit of blood through the arteriovenous loops is very fast, a feature that can be demonstrated with clarity by fluorescein angiography. In some eyes with complex arteriovenous malformations of the retina, one or more of the loops may occlude spontaneously due to kinking of the involved blood vessels.<sup>41</sup> Such an occlusion may result in ischemic or hemorrhagic retinopathy and profound vision loss in the affected eye.

## SYSTEMIC EVALUATION

Baseline assessment of patients who have a complex retinal AVM should probably include MRI and possibly magnetic resonance angiography of the ipsilateral orbit and brain.<sup>42</sup> Such investigation is probably not indicated in patients who have small, limited retinal AVMs unless they have neurological symptoms. Currently, no consensus exists about what constitutes appropriate follow-up of affected patients.

## TREATMENT

No effective treatment is currently available for retinal AVMs. Complex, symptomatic intracranial AVMs can sometimes be managed effectively by intracranial resection, arterial ligation, arterial embolization, stereotactic radiosurgery, or charged particle beam irradiation.<sup>43,44</sup>

## COURSE AND OUTCOMES

Life expectancy is reduced in patients who have WMS because of early deaths attributable to spontaneous bleeding from the intracranial AVMs<sup>38,39</sup> and strokes related to their treatment.<sup>43</sup> In addition, the affected eye is sometimes blinded as a result of spontaneous occlusion of the retinal AVM.<sup>41</sup>

# Principles of Imaging in Neuro-Ophthalmology

Swaraj Bose

## 9.1

**Definition:** Computed tomography (CT), magnetic resonance imaging (MRI), MR and CT angiography (MRA, CTA), conventional catheter angiography, and functional imaging including positron emission tomography (PET), functional MRI (fMRI), and ultrasonography (US) are important in the neuro-ophthalmic evaluation of the anatomical, pathological, vascular, and functional status of the eye, orbit, visual pathways, brain, and ocular motor system.

### Key Features

- Recent advances in neuroimaging have revolutionized patient management in neuro-ophthalmology.
- CT scans use ionizing radiation but are advantageous in detection of acute intracranial hemorrhages and bony lesions.
- MRI uses different pulse sequences to identify the anatomy and pathology of the visual system and its disorders.
- Defines and differentiates central nervous system vascular pathologies using MRA, MR venogram, CTA, CT venogram, and catheter angiography.
- Functional studies including PET, single-photon emission computed tomography (SPECT), and fMRI identify changes in the metabolic and perfusion states of the brain.
- Neuroimaging results should be interpreted in association with history and clinical findings.

## INTRODUCTION

### Ophthalmologist's Role in Neuroimaging

Although neuroimaging is an integral part of the diagnostic criteria and/or prognostic data in neuro-ophthalmological diseases, ancillary testing should be used in conjunction with, not as a substitute for a thorough clinical evaluation. For example, a positive MRI finding of a plaque lesion is both diagnostic and prognostic for patients with demyelinating optic neuritis,<sup>1,2</sup> whereas presence of a single plaque without any clinical signs would not necessarily prove to be demyelinating in origin. The optic neuritis treatment trial (ONTT study) concluded that the 10-year risk of multiple sclerosis following an initial episode of acute optic neuritis was significantly higher if there was a single brain MRI lesion. Also, a negative neuroimaging is one of the criteria for making a diagnosis of pseudotumor cerebri or idiopathic intracranial hypertension.<sup>3</sup> Furthermore, live three-dimensional localization of orbital and intracranial tumors have improved the results of surgery, whereas PET and fMRI have improved our understanding of the functional basis of pathology.

## COMPUTED TOMOGRAPHY

### Principles

The scanning assembly in computed tomography consists of an X-ray detector on one side of the patient, rigidly connected to a collimated source of X-rays on the other side. The X-ray tube and the detector move around the patient as a single unit and cross-sectional images can be acquired at different tissue levels such as near the top of the skull or at the skull base. The computer then reconstructs the image from data points that are

TABLE 9.1.1 CT Versus MRI of Orbit

CT	MRI
Coronal and axial views	Multipplanar imaging including sagittal views
Excellent for bone and bony lesions, sinuses	Excellent soft tissue delineation
Useful in assessing retro-orbital mass in proptosis	Fat suppression with contrast essential for assessment
Calcification seen well	Retro-orbital fat is bright and contrasts with low signal of surrounding bone
Indications: orbital inflammation, trauma, tumor, thyroid ophthalmopathy, disc drusen, foreign body	Orbital tumor, optic nerve glioma, orbital apex, and parasellar lesions

CT, Computed tomography; MRI, magnetic resonance imaging.

assigned a numerical value based on the attenuation of the X-ray beams and represented as pixels. This attenuation coefficient (in Hounsfield units [H]); it ranges from -1000 H for air, to +1000 H for dense bone) provides a numerical matrix that helps the computer reconstruct the image. To display the values of each data point in a meaningful way on photographic film, gray scales are chosen in which each contrast change represents a range of attenuation coefficients.

### Clinical Applications

CT scans are most useful in the detection of orbital disorders (thyroid, trauma, infection, and tumor, sinus, and lacrimal diseases), acute intracranial bleeds, bony abnormalities, and fractures of the orbit and skull.<sup>4</sup> The advantages include rapid image acquisition, relatively low cost, wide availability, and excellent spatial resolution;. Newer generation helical and spiral CT scanners employ thinner sections, less volume averaging, faster scan times, decreased motion artifact, reduced radiation exposure, and new reconstruction algorithms that enable multiplanar reformations. The disadvantages of CT are patient exposure to radiation, lack of sagittal imaging, potential intravenous contrast reactions, and dental and bony artifacts (Table 9.1.1).

### Safety

CT scans do produce ionizing radiation; the national recommended dosages are below 150 milliGray (mGy) per scan. The adjunctive intravenous injection of iodinated contrast provides enhancement in cranial CT to areas of increased vascularity and to areas of blood-brain barrier breakdown, through which seepage of iodinated contrast occurs. Although the contrast is used to detect intracranial extension of orbital tumors and evaluation of chiasmal and parachiasmal lesions, use of these agents must be weighed against their risks, including allergic reactions, nephrotoxicity, and anaphylactic shock, which can be life threatening.

## MAGNETIC RESONANCE IMAGING

### Principles

MRI is based on the principle of nuclear magnetic resonance, in which the nuclei of certain atoms become aligned or polarized when placed in a strong magnetic field, and the subsequent information from magnetic field gradients can be translated into position-dependent image maps.

**Fig. 9.1.1 Magnetic Resonance Behavior of Protons.** In the absence of an external magnetic field, the spin orientation of free protons is random. In a strong magnetic field, the free protons become aligned with their magnetic axis parallel (or, less often, antiparallel) to the magnetic field. Exposure to a brief radiofrequency pulse at the Larmor frequency changes the alignment of the free protons' spin axes. After the radiofrequency pulse, the free protons twirl like tops around the lines of force of the magnetic field with a motion called precession.

When body tissue is placed in a strong magnetic field, the magnetic axes of a small percentage of randomly oriented, mobile hydrogen atoms (protons distributed in the body water) align parallel (and some antiparallel) to the magnetic field (Fig. 9.1.1). The precession frequency is dependent on the strength of the external magnetic field. Thus, the stronger the magnetic field (higher Tesla), the higher the precession frequency. During this state, there are more protons aligned parallel to the external field, resulting in a net magnetic moment aligned with or longitudinal to the external magnetic field (see Fig. 9.1.1, second from top). An exposure to a brief radiofrequency (RF) pulse at the same frequency as the precessing protons causes resonance or transfer of energy to the protons. This results in more protons being antiparallel and thus neutralizing more protons in the opposite direction. The consequence is a decrease in the longitudinal magnetization. The RF pulse can also cause the protons to precess in phase or be synchronous, resulting in a new magnetic vector called the *transversal magnetization*. Computer analysis is used to encode spatial localization and an image is created.<sup>5</sup>

## Imaging Parameters

### T1 and T2

When the RF pulse is switched off, the longitudinal magnetization increases and the transversal magnetization dissipates. The longitudinal relaxation is described by the time constant T1, the longitudinal or spin-lattice relaxation time. The transversal relaxation is described by the time constant T2, the transversal or spin-spin relaxation time. T1 depends on tissue composition, structure, and surroundings and is an expression of the time it takes for the energy imparted by the RF pulse to be transferred to the lattice of atoms that surround the nuclei. T1-weighted images are good for delineating anatomy, as fluid appears dark ("black" vitreous, looks

**TABLE 9.1.2 T1 and T2 Signal Characteristics of Common Tissues and Materials**

	T1 Signal	T2 Signal
Air	Dark	Dark
Bone		
Dense calcification		
High protein	Bright	Dark
Paramagnetic substances (e.g., gadolinium, melanin)		
Fat	Bright	Dark (bright on fast spin echo)
Water	Dark	Bright
Edema		
Vitreous		
Cerebrospinal fluid		
Very viscous protein	Dark	Dark
Fibrosis		
Dura mater		
Ligaments		
Muscle	Light gray	Dark gray
Nerve		
Gray matter	Dark gray	Light gray
White matter	Light gray	Gray

**TABLE 9.1.3 Image Contrast as a Function of the Repetition and Echo Times**

	Short Repetition Time, 300–800 ms	Long Repetition Time, 2000–3000 ms
Short echo time, 10–40 ms	T1-weighted scan	Intermediate scan (proton-density scan)
Long echo time, 60–120 ms	Poor signal-to-noise ratio	T2-weighted scan

like high-definition CT scan) and fat appears bright. Contrast-enhanced images are done with T1 weighting. T2-weighted images are best to discern pathology; fluid is bright ("white" vitreous). The T1 and T2 signal characteristics are summarized in Table 9.1.2.

### TR and TE

Extrinsic parameters may be altered to capitalize on various intrinsic tissue parameters; they include time between RF pulses or repetition time (TR), and the time between the RF pulse and the signal measurement, or the echo time (TE). Alteration of TR and TE creates images that depend more on either the T1 or the T2 characteristics of the tissues (Table 9.1.3). T1-weighted images are created by using relatively short TE and TR, whereas T2-weighted images require a relatively long TE and TR. Images that have a mixture of the T1 and T2 tissue characteristics also may be created by using a long TR and short TE (proton-density image, Fig. 9.1.2).

## Special Sequences and Techniques in the Production of an Image

### Spin Echo, Gradient-Echo, Fluid-Attenuated Inversion Recovery, and Fat Suppression

Fast spin echo (SE) techniques reduce motion artifact but are inferior to SE in the detection of hemorrhage or small lesions that have weak signal strengths. Gradient echo (GRE) protocols have a shorter TR (which allows faster imaging), a high signal-to-noise ratio (which allows thinner slices), and provide flow-related enhancement (which can be used to form images for MRA). Fluid-attenuated inversion recovery (FLAIR) techniques diminish the signal from protons of particular substances that are relaxed only partially to a perpendicular orientation to the main magnetic field, such as fat in short time interval inversion recovery and in spectral presaturation inversion recovery sequences or cerebrospinal fluid (CSF). They also help to reveal demyelination plaques in the central nervous system, which often are not visible on routine MRI (Fig. 9.1.3).<sup>6</sup>

Fat suppression is a technique that deletes the fat and utilizes two techniques: (1) STIR—short time inversion recovery, and (2) CHESS—chemical-shift-selective fat suppression, also called fat-sat, which is very useful when combined with intravenous contrast. This allows small orbital lesions, the pituitary, and around the skull base (which has fat in the bone marrow) to be visualized but also may introduce artifacts, particularly in the lower aspects of the orbit.<sup>7</sup>

**Fig. 9.1.2 Comparison of Image Contrast.** (A) T1-weighted image. (B) T2-weighted image. (C) Proton-density image. (D) Fat suppression reducing the normal bright signal of orbital fat in T1-weighted images and improving contrast between fat, optic nerve, and extraocular muscles. (Courtesy Dr. Ramon Figueroa.)

**Fig. 9.1.3 Fluid-Attenuated Inversion Recovery (FLAIR).** FLAIR sequences help reveal demyelination in the central nervous system that often is not visible on routine magnetic resonance imaging (arrow). (Courtesy Dr. Ramon Figueroa.)

### Diffusion-Weighted Imaging

By measuring the phenomenon of slow water diffusion in tissues (which generally increases in pathological states), diffusion-weighted images (DWI) help in the evaluation of cytotoxic edema, demyelinating plaques, inflammation, tumors, and early brain infarction and in defining internal tissue architecture.<sup>8</sup>

### Contrast Enhancement

Gadolinium is the most commonly used MRI contrast material. It is natively a toxic metal ion, but when chelated with diethylenetriamine

pentaacetic acid (DTPA), its toxicity is reduced but its paramagnetic properties are retained and its biodistribution characteristics mimic those of iodinated contrast media used in CT scans. The chelate remains extracellular, does not cross the intact blood–brain barrier, and is excreted renally. In pathological states, the chelate tends to move from the intravascular to the extracellular space and thereby highlights pathological processes.

Because it shortens the T1 relaxation time, gadolinium typically is used for T1-weighted imaging, in which it provides a bright signal. For orbital studies, T1-weighting techniques are combined with a fat suppression technique to enhance lesions so that they may be differentiated from the otherwise bright orbital fat signal (see Fig. 9.1.3).<sup>9,10</sup> Gadolinium-DTPA is usually used in the form of its dimeglumine salt at a dose of 0.1 mmol/kg. Gadolinium has an excellent safety record, relative contraindication is hemolytic or sickle cell anemia, and rare serious reactions are hives, bronchospasm, and asthmatic attack. Other side effects include headache, hypotension, or a transient rise in serum iron or bilirubin levels. However, development of nephrogenic systemic fibrosis among patients with severe renal insufficiency following exposure to gadolinium is approximately 4% and mortality can reach 31%. The mechanism is unclear, but this technique should not be used in patients with renal insufficiency or if the calculated glomerular filtration rate is less than 60 mL/minute/1.73 m<sup>2</sup>.<sup>11</sup>

### Surface and Head Coils

The placement of receiver coil antennae close to the tissues to be scanned may provide much stronger signal acquisition and thus allow thinner sections, better resolution, and shorter scan times that provide high-resolution visualization of the globe, orbital apex, optic nerve, and chiasm.

### Magnetization Transfer Imaging

Magnetic transfer imaging capitalizes on the effect large proteins have on the transfer of energy between bound and unbound water protons. The benefits of magnetization transfer are greatest in tissues that have high macromolecular concentrations (e.g., brain, muscle) rather than those that have low macromolecular concentrations (e.g., fat). Magnetic transfer contrast sequences improve the detection of brain lesions such as cerebral metastases, and the best differentiation of demyelinating plaques from edematous lesions is effected with magnetization transfer techniques combined with gadolinium enhancement.<sup>12</sup>

**Fig. 9.1.4 Magnetic Resonance Angiography of the Circle of Willis.** (Courtesy Dr. Ramon Figueroa.)

## Safety

Physical injury may occur in the presence of implanted ferromagnetic bodies because these could be transformed into projectiles due to the strong magnetic fields used in MRI. Ferromagnetic, metallic, intraocular, intraorbital, or intracranial foreign bodies; cochlear implants; intracranial aneurysm clips; cardiac pacemakers; and defibrillators are contraindications for MRI.<sup>13</sup> Most neurosurgical clips are not ferromagnetic, and those placed in other locations (e.g., episcleral tantalum clips used in retinal detachment surgery and for proton beam irradiation) are not a contraindication. When unsure, CT scans may be carried out to screen for such objects.

## ANGIOGRAPHY

### Magnetic Resonance Angiography

#### Principles

MRA utilizes three basic techniques: time of flight (TOF) MRA, phase-contrast (PC) angiography, and gadolinium-enhanced MRA (GDx-MRA). These approaches share two basic steps: acquisition of flow-sensitive image of vessels with suppression of stationary background to enhance vascular anatomy, and production of 2-dimensional images from 3-dimensional volume image data. TOF utilizes a gradient-echo technique that relies on inflow-related signal enhancement of vessels, whereas PCA utilizes a similar technique to detect velocity-induced phase shifts that distinguish flowing blood from stationary tissues. A newer hybrid technique, multiple overlapping thin slab acquisitions, combines the advantages of 2-dimensional and 3-dimensional modes for TOF acquisitions because it limits signal drop-off yet retains high resolution.<sup>14</sup> MRA is not a simple display of vascular anatomy. Instead, it extrapolates physiological data obtained from flow characteristics of protons to demonstrate anatomy. Thus the diameter of the blood vessels sometimes may appear smaller when using MRA than with conventional or CT angiography.

#### Clinical Applications of MRA

These include evaluation of the extracranial (carotid stenosis, plaques, and dissections in the evaluation of transient visual loss) and the intracranial circulations (aneurysms, arteriovenous malformations, occlusive disease, and carotid fistulas). MRA is an excellent noninvasive technique for detecting asymptomatic aneurysms measuring greater than 5 mm (Fig. 9.1.4). Limitations of MRA include poor detection of aneurysms less than 5 mm in diameter, false-positive results in tightly wound vessel loops, and a tendency to over-interpret vessel stenosis.

### Computed Tomographic Angiography

#### Principles

CTA utilizes an intravenous bolus injection of iodinated contrast followed by high-speed spiral CT scan with computer-generated 3-dimensional images of medium-sized and large-sized arteries. The advantages of CTA over standard MRA are the rapidity of examination and images of the true lumen (rather than flow within a vessel) and the ability to be performed in patients with claustrophobia, pacemakers, and older aneurysm clips<sup>15</sup> (Fig. 9.1.5).

**Fig. 9.1.5 CT Angiogram of the Carotids.** Note the simultaneous demonstration of the surrounding bony landmarks.

#### Clinical Applications

Detection of aneurysms as small as 1.7 mm, superior imaging of the neck of the aneurysm, better delineation of surgical anatomy, characterization of mural thrombi, detection of vasospasm, arterial stenosis, and carotid-cavernous fistulas, and provision of rotating 3-dimensional images are the major clinical uses.<sup>16</sup> Limitations include difficult detection and delineation of cavernous sinus and posterior inferior cerebellar artery aneurysms, feeding vessels for dural carotid-cavernous fistulas, and risks arising from radiation exposure and contrast agents.

#### CTA Versus MRA

In the management of patients with intracranial aneurysms—and especially for the evaluation of patients with painful partial third nerve palsy to rule out posterior communicating artery (PCOM) aneurysms—the commonly asked question is: Which imaging is superior, CTA or MRA? Sometimes the easy answer is that it depends on the local institutional expertise and the neuroradiologist reading the films, but clinical data have shown that contrast-enhanced 3Tesla MRA was comparable in image quality to time of flight MRA (TOF-MRA) and CTA.<sup>17</sup> However, other reports have shown that a 7-mm PCOM aneurysm was missed by brain MRI and MRA but detected by CTA.<sup>18</sup> Also, CTA was found to be a better procedure for traumatic aneurysms with skull base fractures.<sup>19</sup>

### Conventional Angiography

#### Principles

Conventional percutaneous cerebral angiography (usually via the femoral artery) remains the gold standard for accurate detection and localization of small intracranial aneurysms with or without subarachnoid hemorrhage. Interventional neuroimaging involves the introduction of coaxial systems of extremely flexible microcatheters, balloons, coils, and other devices in the cerebral vascular system for therapeutic purposes; it is used commonly for aneurysms, arteriovenous malformations and carotid-cavernous and dural fistulas using GDCs (Guglielmi detachable coils, Target Therapeutics, Fremont, CA)<sup>20</sup> (Fig. 9.1.6). Digital subtraction angiography (DSA) is a technique that reduces artifacts by subtracting densities created by the overlying bony skull and uses smaller amounts of dye. The contrast dye outlines the column of flowing blood within the injected vessel and demonstrates stenosis, aneurysms, vascular malformations, flow dynamics, and vessel wall irregularities such as dissections or vasculitis. Morbidity (~2.5%) is primarily related to ischemia from emboli or vasospasm, dye-related reactions, or complications at the arterial puncture site (e.g., hematoma).

## Ultrasonography

### Principles

Ultrasonographic technology is based on the reflection of ultrasound waves (5–20 MHz) at acoustic interfaces and is used in neuro-ophthalmology for the evaluation of orbital pathology such as mass lesions, inflammatory-congestive processes (see Chapter 9.23), and foreign bodies. B-Scan US provides a useful, inexpensive, rapid, and easily tolerated method to distinguish solid from cystic orbital lesions, to show an enlarged superior ophthalmic vein and extraocular muscles, and to distinguish and demonstrate an optic nerve head drusen from true dilatation of the optic nerve sheath in papilledema.<sup>21</sup> Also, transcranial Doppler imaging can be used to assess patency and location of the temporal artery for patients being evaluated for temporal arteritis.<sup>22</sup>

## FUNCTIONAL IMAGING

### Positron Emission Technology and Single-Photon Emission Computed Tomography

#### Principles

PET and SPECT are performed with systemically administered isotopes (such as 18F-fluoro-2-deoxyglucose [FDG], 13N ammonia [13NH<sub>3</sub>], fluoride-18 [18F]) that emit protons. They are used to image biological processes that measure regional cerebral blood flow and glucose consumption and thus, indirectly, tissue metabolism.<sup>23</sup> These techniques trace the transport and phosphorylation of glucose, and the glucose-linked positron emits two photons that strike detectors placed around the head. The greater the rate of glucose metabolism of the tissue, the more photons are emitted. Glucose metabolism provides about 95% of the adenosine triphosphate required for brain function. FDG is taken rapidly into the intracellular compartment, but it cannot diffuse from the brain because its metabolism stops following its phosphorylation to deoxyglucose-6-phosphate. Therefore, FDG remains trapped intracellularly and thus is an excellent agent to use for cerebral metabolism imaging. Tomographic images are obtained in a manner similar to those for MRI or CT scanning. Cerebral blood flow, oxygen utilization, and glucose utilization may be measured. PET scanning is used mainly for evaluation of ischemia/stroke, tumors, migraine, blepharospasm, cortical visual loss, and mapping of the visual cortex, among others.<sup>24</sup> The shortcoming of PET is its relatively poor resolution of 57 mm, cost, and limited availability because of the requirement for close proximity to a cyclotron to produce the radioisotopes.

In SPECT, isotopes such as iodine-123 iodoamphetamine or technetium-99 are incorporated into biologically active compounds, and CT plots their distribution. The information provided by SPECT is similar to that of PET, but SPECT does not require the use of isotopes produced in a cyclotron. However, resolution is even poorer with SPECT. The future of these technologies is very bright, and with the recent advent of micro-PET, higher resolution receptor and genetic imaging will provide greater understanding of the workings and abnormalities of the human brain (Fig. 9.1.7).

**Fig. 9.1.7** (A) PET images in a subject demonstrated metabolic increases (red) and decreases (blue) in the brain. (B) Functional magnetic resonance imaging (fMRI) obtained with a 3Tesla magnet demonstrating the images generated following a visual task.

### Clinical Applications

Current applications of functional imaging include detection of hypermetabolic states associated with tumor, differentiation of tumor from areas of radiation necrosis, localization of seizure foci, detection of ischemic regions, evaluation of biochemical changes associated with cognitive and psychiatric abnormalities and their response to pharmaceutical intervention, and drug localization in the brain.<sup>25</sup>

## Magnetic Resonance Spectroscopy

### Principles

Magnetic resonance spectroscopy (MRS) is used for diagnostic biochemistry in vivo and is based on the same principle previously used in analytical chemistry to obtain MR spectra. MRS studies of cerebral ischemia are confined solely to proton (1H) and phosphorus-31 (31P) because of their intrinsically higher sensitivity compared with other nuclear species. Neurospectroscopy (proton MRS, which has higher sensitivity than 31P MRS), uses a small voxel size (1 cm<sup>3</sup>) and enables the detection of compounds such as N-acetylaspartate, creatine, choline, lactate, and inositols (Fig. 9.1.8). Each metabolite has a “signature” that, when added to the other major metabolites, results in a complex spectrum of overlapping peaks.<sup>26</sup> Pathologies documented by MRS include brain tumor, stroke, focal cerebral lesions, multiple sclerosis, and intracranial hemorrhage. An acutely ischemic brain produces lactate by anaerobic metabolism during the first

23 days after injury, which can be detected by MRS. With the advent of MRS and using multi-MR modalities (MRI, MRA, perfusion MR), it is now possible to evaluate extensively not only regions of cerebral injury but also regions at risk of infarction.<sup>27</sup>

## Functional Magnetic Resonance Imaging

### Principles

fMRI is a less invasive technology for mapping cerebral cortical activation in response to performing specific cognitive, sensory, or motor tasks. The basis for most fMRI is measurement of increases in blood oxygenation level during the performance of specific tasks (BOLD: blood oxygen level dependent).<sup>28</sup> This method utilizes the change in magnetic susceptibility of hemoglobin as it changes from oxyhemoglobin (diamagnetic, reduces magnetic field into which it is placed) to deoxyhemoglobin (paramagnetic, increases magnetic field), which results in T2 shortening. The advantage of this technique is that no injection is required. fMRI is evolving rapidly into a useful experimental and clinical tool for functional cortical mapping, psychophysical tests, brain tumor mapping, and understanding the basis of higher visual functioning.<sup>29</sup>

## IMAGING STRATEGIES IN NEURO-OPHTHALMOLOGY

Choosing the correct imaging modality should be based on the differential diagnosis, nature of suspected lesion, patient characteristics, and the available modalities. To obtain the most meaningful neuroimaging results, communication with the neuroradiologist is vital and should include providing adequate history, type of scan, sequence, contrast material, scan thickness, and area of interest. The ordering physicians should explain the procedure, risks, and contraindications to the patient directly.

MRI is usually more valuable than a CT scan in detecting the anatomy and pathology of the lesion and narrowing down the differential diagnosis. However, a CT scan is useful for the evaluation of orbital pathology (tumor, trauma, and thyroid) and in patients with acute intracranial bleeding. Orbital fat provides an excellent contrast with other components on CT and MRI for more precise anatomical localization. Orbital scans require negative angulations that are parallel to the orbital floor, whereas head scans require positive angulations. Gadolinium-enhanced, fat suppression MRI generally best demonstrates pathology of the optic nerve, which includes tumors (such as glioma, meningioma, and hemangioma), radiation damage, demyelinating disease, and inflammatory damage (such as sarcoidosis). We should consider MRA, CTA, and DSA if we suspect a large vessel disease. Optic neuritis studies have found MRI changes to be of diagnostic and predictive value<sup>30</sup> (Table 9.1.4). Papilledema can be evaluated using B-scan US to look for a dilated optic nerve sheath and confirm by a decrease in the diameter of the sheath with abduction (or adduction) of the eye by 30°. MRI of the brain in papilledema may show slit ventricles, and an MR venogram (MRV, a different sequence for veins) may reveal a venous thrombosis. Optic nerve drusen, often calcified, may be seen with B-scan US, CT, MRI, or autofluorescence (for guidelines, see Table 9.1.5).

Combining an understanding of neuro-ophthalmological anatomy with proper imaging techniques provides a powerful method for detecting

**TABLE 9.1.4** Features of CT Versus MRI

CT	MRI
Better for bony lesions	Better for soft tissue delineation
Sensitive to acute hemorrhage	Insensitive
Chronic hemorrhage may be subtle	Well seen
60% acute strokes visualized	80% acute strokes visualized
Posterior fossa degraded by artifact	Well visualized
Poor resolution of demyelinating lesions	Demyelinating lesions well seen at all stages
Metal artifacts (skull plates, clips)	Ferromagnetic artifacts
Axial and coronal images	Axial, coronal, sagittal, and angled images
Iodinated contrast agent	Paramagnetic contrast agent
Risk: ionizing radiation	Risk: magnetic field

CT, Computed tomography; MRI, magnetic resonance imaging.

**TABLE 9.1.5** General Guidelines for the Choice of Neuroimaging Techniques in Neuro-Ophthalmology

Anatomical Location	Clinical Condition	Neuroimaging Technique(s)
Orbit	Tumors Thyroid ophthalmopathy, trauma, hemorrhage, foreign body Optic nerve tumor, orbital apex tumor	US (solid vs. cystic), CT (noncontrast) MRI (soft tissue, fat suppression) Noncontrast CT (preferred imaging) Gd-enhanced, fat-suppressed MRI
Cavernous sinus, chiasm, parasellar region	Tumor Aneurysm (e.g., third nerve palsy) Aneurysm with bleeding	High-resolution contrast CT (fine cuts), MRI Gd-enhanced MRI, MRA, catheter angiography Noncontrast CT scan
Retrochiasmal area and posterior fossa	Aneurysm or AV malformation with bleeding	Noncontrast CT scan
Brain	Intracerebral hemorrhage 1. Acute (intracellular Fe <sup>2+</sup> /methHb) 2. Subacute (extracellular Fe <sup>3+</sup> /methHb) 3. Chronic (methHb/hemosiderin) Papilledema Multiple sclerosis	CT density MRI-T1 MRI-T2 Bright Isodense Hypodense Isodense Hyperdense Hyperdense Dark Hyperdense Hyperdense "B" scan US (optic sheath dilatation) Gd-enhanced MRI, MR venogram Gd-enhanced MRI, T2, FLAIR sequence
Carotids and vertebrals	Stenosis, dissection, plaques, evaluation of amaurosis	Carotid Doppler (US), MRA, CT angiography, catheter angiography
Globe	Optic disc drusen Tumor, trauma, calcification	"B" scan US, noncontrast CT Noncontrast CT

AV, Arteriovenous; CT, computed tomography; Fe<sup>2+</sup>, ferrous iron; Fe<sup>2+</sup>/methHb, iron-methemoglobin; Fe<sup>3+</sup>, ferric iron; FLAIR, fluid-attenuated inversion recovery; Gd, gadolinium; MR, magnetic resonance; MRA, magnetic resonance angiography; MRI, magnetic resonance imaging; US, ultrasonography.

# Optical Coherence Tomography in Neuro-Ophthalmology

## 9.2

Piero Barboni, Nicole Balducci, Giacomo Savini, Michelle Y. Wang

**Definition:** Optical coherence tomography is an ancillary test that documents the morphology of the optic disc and quantifies the nerve fiber layer, macular ganglion cells, and other retinal layers.

### Key Features

- Noninvasive, noncontact, reproducible, and quantitative.
- Defines and differentiates specific forms of optic neuropathy.
- Documents changes in retinal nerve fiber layer (RNFL) and macular ganglion cell layer (GCL) thickness over time.
- Helps to correlate structural RNFL and macular GCL changes with visual function.
- Optical coherence tomography angiography (OCTA) is a new tool that visualizes the microvascular network of optic nerve head, peripapillary and retina.

### INTRODUCTION

Optical coherence tomography (OCT) is a noninvasive, noncontact, imaging technology that provides high-quality in vivo resolution of the retina and the optic nerve head. It has been widely used in neuro-ophthalmology for several purposes, including defining and differentiating specific forms of optic neuropathy, quantifying changes in RNFL and macular GCL thickness over time, and correlating structural changes with visual function. OCT analysis of the RNFL and GCL thickness is a useful biomarker for disease diagnosis and management.<sup>1</sup> For a more comprehensive explanation of the use of OCT in central nervous system diseases, please refer to a recent publication.<sup>2</sup>

### OCT INTERPRETATION

In neuro-ophthalmology, two main structural measures of optic nerve function are provided by OCT: peripapillary RNFL and macular GCL thickness. The combined results of RNFL and GCL thickness aid both diagnosis and monitoring of the optic nerve diseases.

#### Peripapillary Retinal Nerve Fiber Layer

The RNFL thickness is usually measured via a circular scan 3.4 mm from the center of the optic disc, as this distance reduces inter-individual variability related to the location of the vessels and the shape of the optic disc.<sup>3-4</sup> OCT software provides data on average and sectorial RNFL thickness in micrometers, analyzed by quadrants, clock hours, or finer sectors. Early, and even subtle, RNFL changes are often detectable by the deviation map (where RNFL thickness is compared to normal age-matched population)<sup>5</sup> and by the thickness map (which reports absolute thickness values not based on the normative database comparison).<sup>6</sup> Some OCT devices also provide information on the sizes of optic disc, neuroretinal rim, and optic cup.

#### Macular Ganglion Cells Layer

The macular GCL layer is thickest in the macula,<sup>7</sup> accounting for 30% of the entire macular thickness. Its thickness is not influenced by inter-individual variability of optic disc shape or by the presence of large retinal vessels and glial elements. In some cases, GCL thickness is reduced before RNFL

**Fig. 9.2.1 Microcystic Inner Nuclear Layer Abnormalities.** Case of a 45-year-old man affected by dominant optic atrophy, where microcysts in the nuclear layer are well detectable at the level of vitreo-retinal adhesion (*top and middle figures*). Note that the microcysts disappear where the vitreo-retinal adhesion is not seen (*bottom figure*).

thinning, and its measurement is particularly useful for recognizing axonal loss during optic disc edema, where RNFL swelling can mask retinal nerve fiber loss.<sup>8-10</sup>

Most OCT devices provide analyses of the macular GCL, providing data on average, minimum, maximum, and sectorial macular GCL thickness. Deviation and thickness maps are also available in some devices.

#### Microcystic Inner Nuclear Layer Abnormalities

Microcystic macular edema (MME) is present in 5%–25% of patients with optic neuropathy. It is characterized by the presence of microcystic changes in the inner nuclear layer, which may cause reduction in visual acuity. MME is easily identified in the perifoveal region with spectral-domain OCT (SD-OCT) (*Fig. 9.2.1*).<sup>11</sup> Typically MME is not identifiable on fundus examination. This finding is nonspecific insofar as it has been associated with various optic neuropathies, such as multiple sclerosis (MS),<sup>12</sup> neuromyelitis optica,<sup>13-14</sup> posterior ischemic optic neuropathy,<sup>15</sup> Leber's hereditary optic neuropathy,<sup>16</sup> and dominant optic atrophy.<sup>17</sup>

Various hypotheses have been postulated, including retrograde trans-synaptic degeneration in the visual pathways,<sup>18,19</sup> vitreo-macular traction,<sup>20,21</sup> Muller cells dysfunction,<sup>11</sup> and inflammation.<sup>12</sup>

### PAPILLEDEMA

Papilledema occurs when increased perineural pressure produces axoplasmic flow stasis, causing swelling of the optic nerve fibers at the level of

**Fig. 9.2.2** In the same patient shown in Fig. 9.2.1, a vertical scan through the optic nerve shows a lazy V pattern of the subretinal space inferior to the optic nerve.

the optic disc. A number of studies have evaluated optic disc edema using OCT. Swelling of the peripapillary RNFL is the most relevant finding.<sup>22</sup> Since errors in defining the outer border of the RNFL may occur in the most advanced cases due to a decreased signal-to-noise ratio, analysis of the whole peripapillary retinal thickness has been proposed as a potential alternative method to quantify edema of the optic nerve.<sup>23</sup> A subretinal hyporeflective space can also be visualized around the optic nerve head (ONH) in cases of disc edema. Cross-sectional images of the ONH reveal that such a space has a “lazy V” pattern (thickest near the ONH and tapering away from the ONH, Fig. 9.2.2). This characteristic pattern helps to differentiate disc edema from optic disc drusen, in which a “lumpy-bumpy” internal contour is seen.<sup>24</sup> Recent analyses of the subsurface architecture of the ONH have found that in the case of high intracranial pressure, the peripapillary retinal pigment epithelium is flexed toward the vitreous as a result of increased intracranial pressure, which influences the architecture of the neural canal opening.<sup>25</sup> OCT is therefore helpful in detecting and characterizing disc edema, but it alone cannot differentiate generalized disc edema from more specific papilledema.

A study performed on children with craniosynostosis and hydrocephalus showed that quantitative measures of the peripapillary retinal structure by OCT correlated with intracranial pressure.<sup>26</sup> The analysis of macular GCL thickness can detect fiber loss when the optic disc is still swollen, which can help differentiate axonal loss from resolution of RNFL swelling in cases of improving papilledema.<sup>8</sup>

### Nonarteritic Ischemic Optic Neuropathy

OCT is useful in both the edematous and atrophic stages of nonarteritic ischemic optic neuropathy (NAION). In the early stages, optic disc edema—principally caused by increased water content within axons and in the interstitial tissue—is the major clinical sign. OCT studies show that the peripapillary RNFL is thickened and a hyporeflective subretinal space can be detected around the ONH (see Fig. 9.2.2).<sup>22</sup> Later, when optic disc atrophy develops, the RNFL becomes thinner, even in the sectors corresponding to the relatively unaffected hemifield of the visual field.<sup>27</sup>

Different patterns of RNFL involvement can be observed, depending on the clinical features of NAION. In patients with visual field (VF) defects confined to the inferior hemifield, OCT shows thinning in the superior, nasal, and temporal RNFL quadrants. In patients with diffuse VF loss, thinning is seen in all RNFL quadrants. In patients with a central VF defect, the RNFL thinning is limited to the superior and temporal quadrants.<sup>28</sup> OCT has also been used to evaluate the characteristics of the ONH in patients with NAION. Ophthalmoscopic findings of crowded disc (e.g., lower cup-to-disc ratio) have been confirmed by OCT.<sup>29</sup> The peripapillary retinal pigment epithelium is not flexed toward the vitreous, as usually seen in papilledema.<sup>4</sup>

The analysis of macular GCL thickness can detect fiber loss when the optic disc is still swollen.<sup>9</sup> A significantly greater vertical hemispheric difference in GCL thickness was found in NAION but not in optic neuritis. Recognizing the pattern of altitudinal ganglion cell loss can help in distinguishing the two diseases.<sup>30</sup> There is a strong correlation between the pattern of GCL loss and the location of the VF defect.<sup>9</sup>

## COMPRESSIVE OPTIC NEUROPATHY

Posterior compression of the optic nerve can produce optic disc edema indistinguishable from papilledema on both clinical examination and OCT testing. Therefore the determination of true papilledema caused by increased intracranial pressure can only be confirmed by lumbar puncture.

In cases of optic nerve tumors or orbital compression, such as Graves' orbitopathy, OCT can be important in recognizing early optic nerve damage and in estimating visual prognosis after treatment. A study conducted in patients with compressive optic neuropathy due to anterior pathway meningioma showed that patients with normal pretreatment RNFL and shorter duration of symptoms are more likely to improve posttreatment.<sup>31</sup> Significant temporal RNFL thinning was detected in patients with chronic dysthyroid optic neuropathy compared to patients with acute dysthyroid optic neuropathy and healthy controls. Moreover, thicker inferior peripapillary RNFL thickness was associated with a better visual outcome.<sup>32</sup> OCT can help differentiate compressive optic neuropathy from glaucomatous optic neuropathy. Recently, a large study found that compressive optic neuropathy is associated with significantly thinner nasal and temporal sectors and thinner cup volume compared with glaucomatous optic neuropathy.<sup>33</sup>

OCT can evaluate the pattern of retinal ganglion cell loss in patients with chiasmal compression. This unique but often subtle pattern of nerve fiber loss is characterized by predominant atrophy of the temporal and nasal fibers of the optic nerve, defined as band atrophy (Fig. 9.2.3). Numerous studies demonstrate that OCT can identify band atrophy caused by chiasmal compression.<sup>34,35</sup> Analysis by OCT shows a diffuse reduction of fiber thickness with preferential involvement of the temporal and nasal sectors (crossing optic nerve fibers), suggesting that the compressive lesion may also affect noncrossing fibers.<sup>36</sup> Comparisons of structure-function in chiasmal compression reveal a good correlation between RNFL and macular thickness and visual field sensitivity, but not between RNFL thickness and pattern electroretinograms.<sup>36–38</sup> Other studies suggest a strong correlation between RNFL and GCL thickness and visual outcome after chiasmal decompression, confirming the prognostic value of OCT.<sup>39,40</sup> Pre- and post-chiasmal decompression OCT analyses have shown a reduction in RNFL and macular GCL thickness in the first 3 months after surgery and an increase in thickness for both measurements in the following 6 months. These results suggest that after surgical chiasmal decompression, progression of the retrograde degeneration is expected in the first 3 months, followed by compensatory changes after 6 months.<sup>41</sup>

### Transsynaptic Retrograde Degeneration in Homonymous Hemianopia

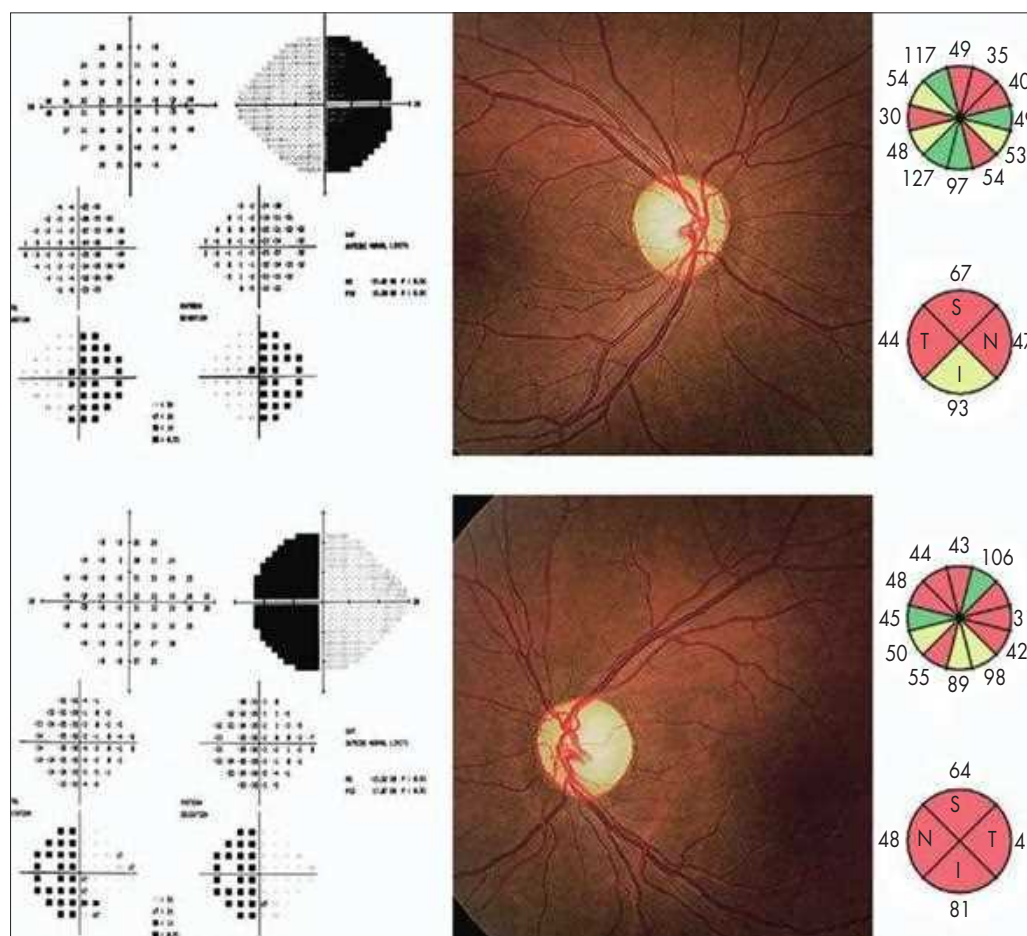

In a study of patients affected by occipital infarction, RNFL thickness reduction was detected as early as 3.6 months after onset.<sup>42</sup> RNFL thinning was found in the superior, inferior, and nasal quadrants in the contralateral eyes and in the superior, inferior, and temporal quadrants in the ipsilateral eyes.

In retrogeniculate lesions, GCL thinning was detected, and the correlation was stronger between visual field defect and GCL thickness than peripapillary RNFL thickness.<sup>43</sup> This correlation is evident also in smaller defects, such as quadrantanopia.<sup>44</sup> In the macula, the topographic distribution of the bodies of the retinal ganglion cells is organized to correspond to VF.

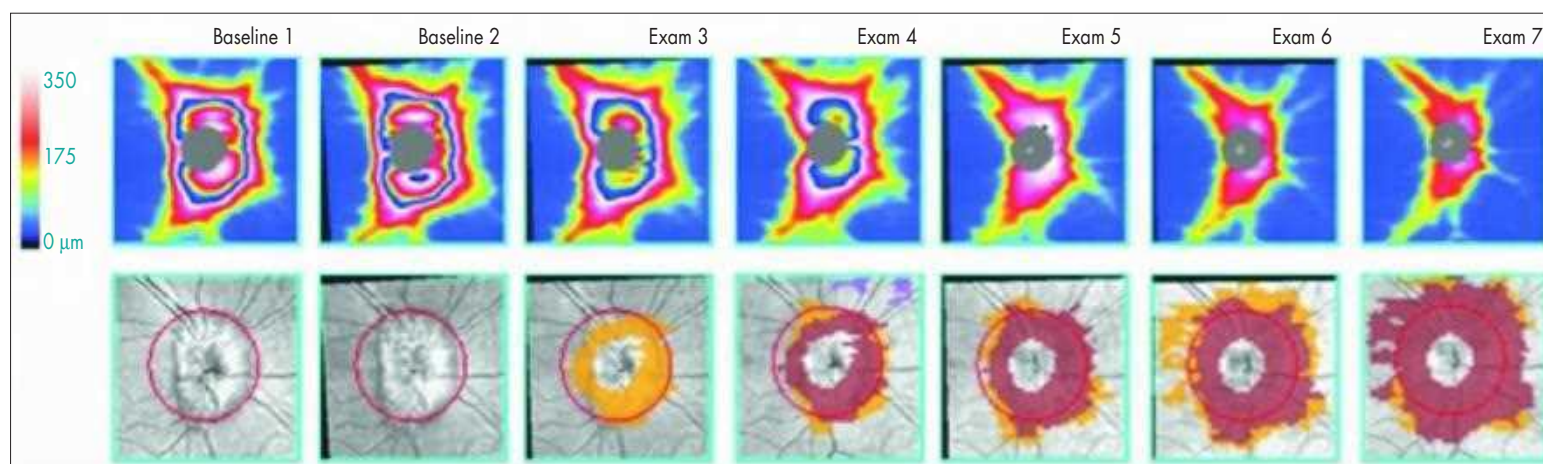

## MULTIPLE SCLEROSIS

Since the first quantitative OCT study of RNFL thickness in MS was published in 1999,<sup>45</sup> there has been rapidly growing interest in various applications of OCT in the diagnosis and management of patients with multiple sclerosis associated optic neuritis (MSON) and multiple sclerosis without optic neuritis (MSNON). OCT has emerged as a potential metric for axonal loss in patients with MS.

In the acute phase of optic neuritis, the peripapillary RNFL thickens as a result of edema, and a hyporeflective space develops in the subretinal space.<sup>22,46</sup> The increase in RNFL thickness resolves in about 1.5 months.<sup>47</sup> Once the acute phase has resolved, the OCT-measured RNFL values are reduced in comparison to normal values (Fig. 9.2.4).<sup>45–50</sup> The earliest evidence of RNFL thinning that can be seen on OCT occurs about 2 months after optic neuritis in the temporal sector, with most RNFL loss occurring within 3–6 months of the ON event. The thickness stabilizes 7–12 months after the onset of optic neuritis.<sup>48,49</sup> Peripapillary RNFL

**Fig. 9.2.3** Visual Field (Left), Optic Nerve Photograph (Middle), and Stratus OCT Results (Right) of a Patient With Band Atrophy of the Optic Nerve. Visual field shows complete temporal hemianopia in agreement with the RNFL loss in the temporal and nasal portions of the optic nerve with relative preservation of the superior and inferior quadrants. (From Monteiro ML, Moura FC, Medeiros FA. Diagnostic ability of optical coherence tomography with a normative database to detect band atrophy of the optic nerve. *Am J Ophthalmol* 2007;143:896–9.)

**Fig. 9.2.4** Optic Nerve Head Analysis in Multiple Sclerosis Shows the Progressive Thinning of Fibers Swelling With Final Diffuse Atrophy.

thinning has also been reported in asymptomatic patients, thus suggesting subclinical axonal damage in the anterior visual pathway in patients with MS-non-ON.<sup>45,51</sup>

A recent study conducted on 879 patients affected by MS showed that patients with peripapillary RNFL less than or equal to 87/88 μm had double the risk of the disability worsening at any time between the first and the third year of follow-up (hazard ratio 2.06). The hazard ratio increased to 3.81 three to five years later.<sup>52</sup>

Longitudinal studies reveal that in some cases, progressive peripapillary RNFL thinning occurs as a function of time and is associated eventually with clinically significant visual loss—with or without a previous history of ON and even in patients with clinically benign MS.<sup>53</sup>

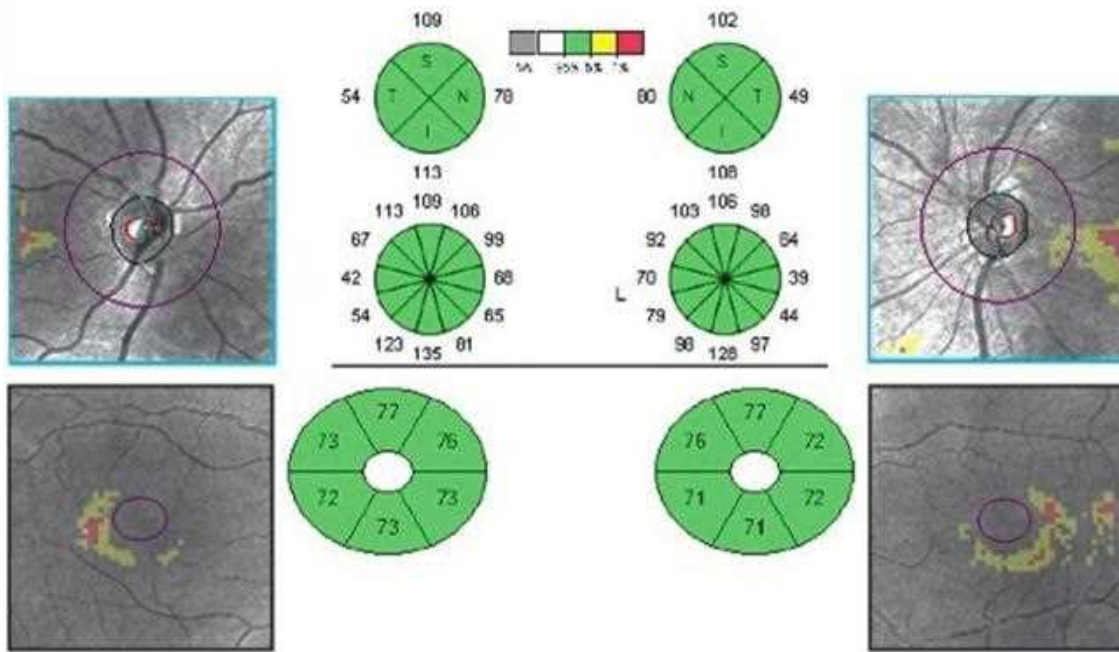

Earlier studies with time-domain OCT showed that ganglion cell loss leads to reduced macular volume in eyes with previous MSON and that macular volume reduction is associated with peripapillary RNFL thinning.<sup>47</sup> Subsequently, SD-OCT studies confirm that eyes of patients with MSON have a thinner macula because of the reduced thickness of the macular RNFL, ganglion cell layer (GCL), and inner plexiform layer (IPL).

Recently, a thinning of all the retinal layers (except for the internal limiting membrane) was reported in patients with MS. Greater effects were

observed in the inner retinal layers (nerve fiber, ganglion cells, inner plexiform, and inner nuclear layers) of eyes with previous optic neuritis ( $P < 0.05$ ).<sup>54</sup> Thinning of the macular RNFL (but not of the GCL and IPL) can also be detected in patients with MS-non-ON patients.<sup>50</sup> The temporal and spatial associations between axonal injury and ganglion cell loss have yet to be determined, although retrograde degeneration of the RNFL has been implicated as the most important mechanism leading to macular damage. In a subset of patients with MS, however, primary disproportionate thinning of the macular inner and outer nuclear layers has been reported in the presence of normal peripapillary RNFL thickness. These patients may present with MS-related macular pathology as a primary process independent of optic nerve pathology.<sup>55</sup> Recently, some studies demonstrated that GCL thickness has better sensitivity than peripapillary RNFL thickness for detecting changes in patients with MS.<sup>56,57</sup> Logistic regression analysis demonstrated that GCL thickness is a potential predictor of axonal damage in MS.<sup>54</sup>

Reduction of peripapillary, macular RNFL, GCL, and IPL thickness is associated with (1) loss of visual function, (2) function disability as measured by the Expanded Disability Status Scale (EDSS), and (3) vision-specific quality of life in MS patients.<sup>50,54,58</sup>

**Fig. 9.2.5 Optical Coherence Tomography in Parkinson's Disease.** Case of a 74-year-old woman affected by mild Parkinson's disease. Note the selective loss of the peripapillary retinal nerve fiber and macular ganglion cells at the level of the papillomacular bundle, detectable only with the deviation maps and not with the sectorial maps.

## OCT and Brain Atrophy

OCT has been regarded as a potential surrogate marker for brain atrophy. A good correlation between average RNFL thickness and lesion volumes in the brain has been found in patients with MS-non-ON, where RNFL thinning may reflect the degenerative process in the brain. The same correlation was not detected in patients with MSON, where axonal loss following ON occurs independently of brain atrophy.<sup>59</sup>

## Neuromyelitis Optica

Neuromyelitis optica (NMO) is a distinct entity from MS, with the highest incidences in Asia.<sup>60</sup> OCT demonstrates a significant reduction of RNFL thickness in patients with NMO compared to healthy controls.<sup>61</sup> The RNFL thickness reduction is well correlated to the visual field damage and the EDSS score. There is also a weak correlation between OCT findings and both visual acuity and visual potential latencies.<sup>61</sup> After a single episode of optic neuritis, the mean RNFL thickness has been found to be lower in patients with NMO than in those with MS, even after adjusting for visual acuity outcome (56.7 vs. 66.6  $\mu\text{m}$ ,  $P = 0.01$ ).<sup>62</sup> When the peripapillary quadrants are compared, the superior and inferior quadrants are thinner in patients with NMO. Moreover, some authors have reported that after a single episode of optic neuritis the mean RNFL thinning was 31  $\mu\text{m}$  in NMO but only 10  $\mu\text{m}$  in MS.<sup>63</sup>

A single subsequent episode of optic neuritis can cause a mean RNFL reduction of 10  $\mu\text{m}$  in NMO but no significant reduction in MS. Moreover, macular volume analysis has shown lower values in NMO compared with MS (5.83 vs. 6.38  $\text{mm}^3$ ,  $P = 0.001$ ). In unilateral cases, the difference between affected and nonaffected eyes has been reported to be greater than 15  $\mu\text{m}$  in 75% of patients with NMO and in 25% of patients with MS. Thus RNFL thinning could be considered a marker of the disease.

The presence of microcystic macular edema at the level of inner nuclear layer is identified in 20%–26% of patients affected by NMO and is correlated with severe disease.<sup>13,64</sup>

## NEURODEGENERATIVE DISEASES

### PARKINSON'S DISEASE

Parkinson's disease (PD) is a common, age-dependent, neurodegenerative disorder characterized by loss of dopaminergic neurons in the substantia nigra. The typical clinical picture of PD includes the presence of motor symptoms, such as bradykinesia, tremor, and rigidity. Nonmotor manifestations, including visual system impairment, are increasingly recognized in PD.<sup>65</sup> The human retina contains dopaminergic amacrine cells, and

retinal dopamine content and metabolites are substantially lowered in patients with PD,<sup>66</sup> so it is not surprising to observe retinal involvement in PD patients.

However, many published studies used OCT to investigate the PD macula have shown contradictory results, probably due to different areas of scanned retina or different algorithms used to quantify thinning.<sup>1</sup> Most studies, however, have at least confirmed one of the first published findings—that the inner retinal layer (including the RNFL, the GCL, and the IPL) is thinner in the macular region of patients with PD compared to healthy subjects, resulting in changes in the slope of the foveal pit.<sup>67,68</sup>
